BEFORE
Scanning electron micrograph (×3300) of *Candida albicans* grown for 48 hours on agar.

Culture

Femstat Prefill destroys the integrity of the yeast cell.

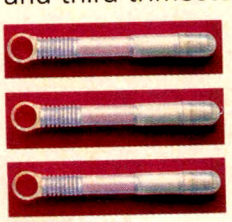
AFTER
Scanning electron micrograph (×3300) of *Candida albicans* on agar plate with butoconazole nitrate.

Shock.

Cure[1]* with 3-day† therapy

■ Microbiological cure rates in 95% of patients eight days following Femstat three-day therapy.[1]

Broad spectrum of activity



■ Clinically effective against *Candida albicans* and other *Candida* species, including *Candida tropicalis.*

Broad margin of safety

■ A low incidence of reported adverse reactions.[2]

■ NOT a triazole/NOT associated with flu-like symptoms.

■ Proven safe and effective for use in pregnant patients† (second and third trimesters only).

3 prefilled disposable applicators

■ Reduces risk of reinfection and ensures unit-dose accuracy.

■ Eliminates messy filling/cleaning procedures.

FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

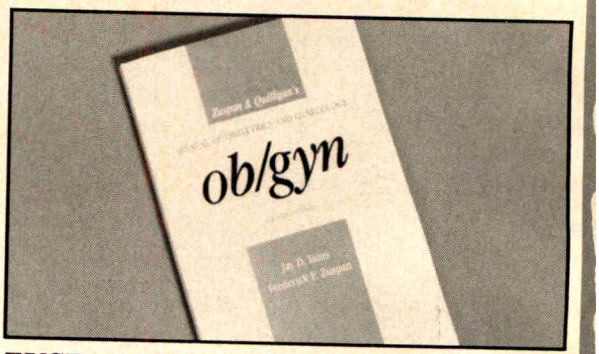
Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.



DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

NEW 2nd EDITION!

ZUSPAN AND QUILLIGAN'S MANUAL OF OBSTETRICS AND GYNECOLOGY

Edited by **Jay D. Iams**, M.D.; **Frederick P. Zuspan**, M.D.; and **Edward J. Quilligan**, M.D.; with 27 contributors.

Completely updated and revised, this new edition features coverage of both gynecology and obstetrics to reflect the increased emphasis both in training and on Board exams. The new outline format and useful summary tables enhance ease of access to important material. Pharmacologic information is more specific, decreasing the need to refer to supplemental references. A concise, graphic/tabular format conveys a maximum amount of information in a minimum amount of space for rapid referral. Key features are: new review questions and answers following each chapter to reinforce key points and assist in Board-exam preparation; expanded coverage of breast feeding, contraception, increased and updated references, and much more; reflects the increased emphasis on gynecologic material in medical training and on Board exams; and a new outline format for easier access to information.

January, 1990. Approx. 464 pages, 105 illustrations.

Triphasil®

Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen
21- and 28-day regimens

MINIMIZES BREAKTHROUGH BLEEDING AND AMENORRHEA

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thrombo-embolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners pre-scribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, con-firming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic mea-sures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

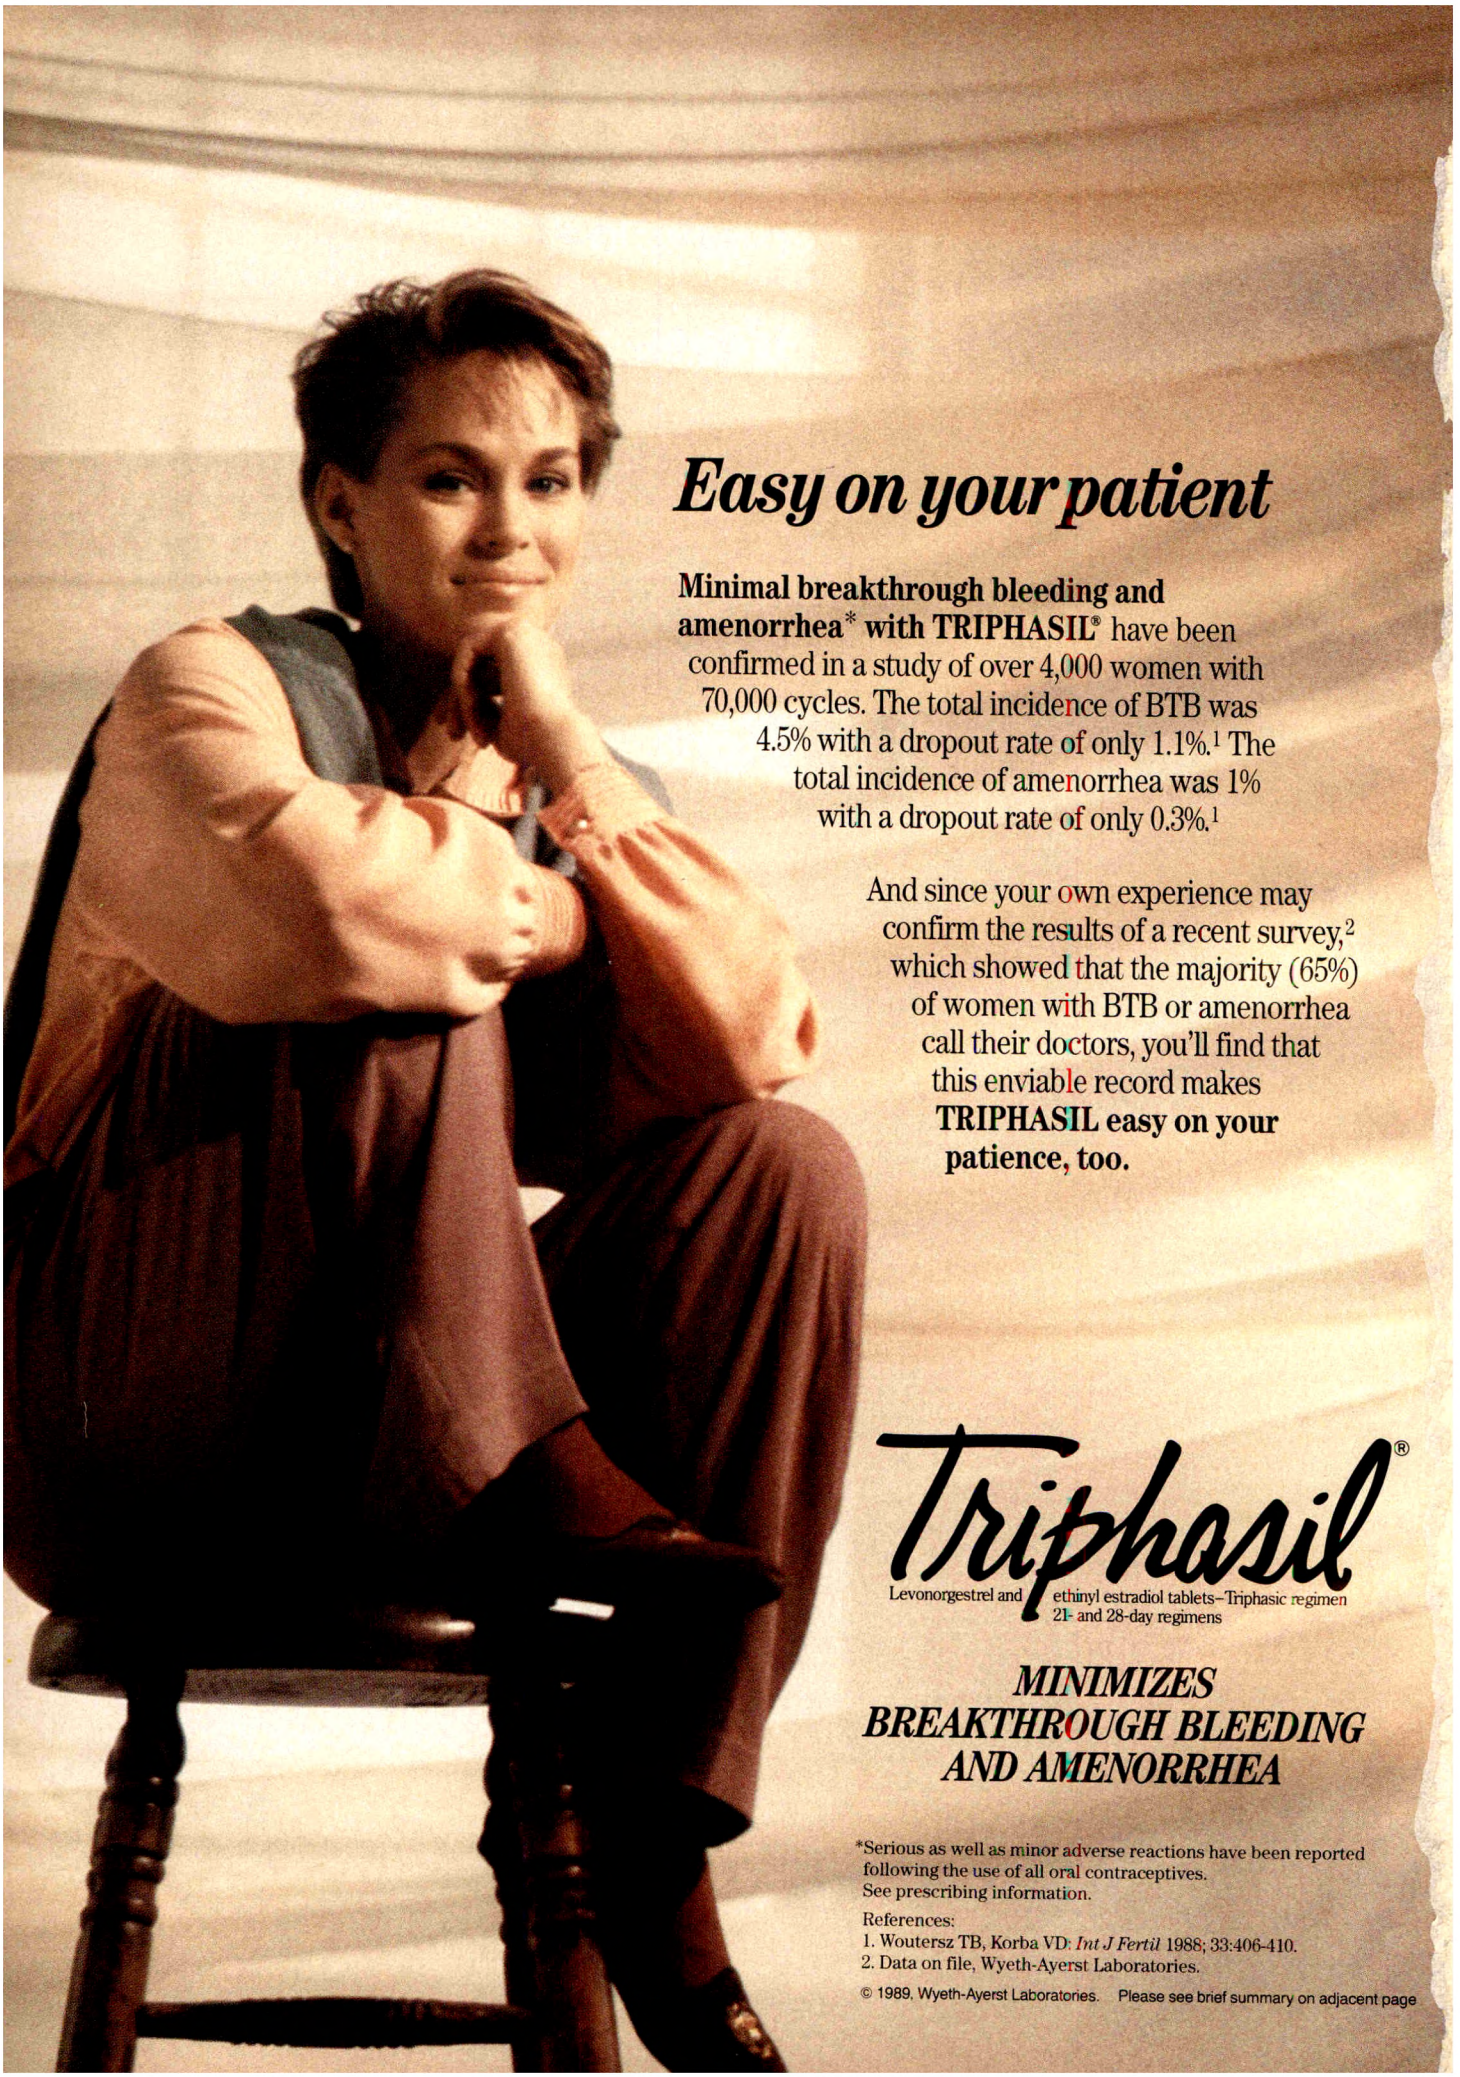
Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)



Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

WYETH: A CARING COMMITMENT TO FEMALE HEALTH

WYETH-AYERST LABORATORIES
Philadelphia, PA 19101

Easy on your patient

Minimal breakthrough bleeding and amenorrhea* with TRIPHASIL® have been confirmed in a study of over 4,000 women with 70,000 cycles. The total incidence of BTB was 4.5% with a dropout rate of only 1.1%.[1] The total incidence of amenorrhea was 1% with a dropout rate of only 0.3%.[1]

And since your own experience may confirm the results of a recent survey,[2] which showed that the majority (65%) of women with BTB or amenorrhea call their doctors, you'll find that this enviable record makes **TRIPHASIL easy on your patience, too.**

Triphasil®

Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen
21- and 28-day regimens

MINIMIZES BREAKTHROUGH BLEEDING AND AMENORRHEA

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.
See prescribing information.

TRANSACTIONS OF THE FIFTY-SIXTH ANNUAL MEETING OF THE PACIFIC COAST OBSTETRICAL AND GYNECOLOGICAL SOCIETY

The tyranny of technology 1365
David C. Figge, MD
Seattle, Washington

Prophylactic intrapartum amnioinfusion: A randomized clinical trial 1370
Thomas H. Strong, Jr., MD, Gretchen Hetzler, MD, Albert P. Sarno, MD, MAJ, USA, and Richard H. Paul, MD
Los Angeles, California

Amnioinfusion in laboring gravid women with oligohydramnios at ≥37 weeks' gestation significantly reduced the incidence of intrapartum morbidity as a result of fetal distress.

Ultrasonography-guided early amniocentesis in singleton pregnancies 1376
Frederick W. Hanson, MD, Regina L. Happ, MD, Frances R. Tennant, PhD, Stacy Hune, MS, and Ann G. Peterson, RN, MN
Davis, California

A total of 527 early amniocenteses were performed with an overall loss rate of 2.3%, of which 0.8% were probably related to the procedure.

Seventy-one quadruplet pregnancies: Management and outcome 1384
Michael S. Collins, MD, and Janet A. Bleyl, BA
Portland, Oregon, and Stockton, California

The epidemiology, management, and outcome of 71 quadruplet pregnancies that occurred between 1980 and 1989 are characterized.

Breast cancer detection: Experience in a suburban community 1393
John A. Goodno, Jr., MD
Arcadia, California

A 32% incidence of nonpalpable breast cancers was found in a review of 669 breast biopsies performed in Arcadia, California, during 1987 and 1988.

Vaginal birth after cesarean or repeat cesarean section: Medical risks or social realities? 1398
E. Paul Kirk, MD, Kathleen A. Doyle, MD, Janet Leigh, MD, and Mary L. Garrard, MSN
Portland, Oregon

A woman's choice of vaginal birth after cesarean section or elective repeat cesarean may involve social factors more than medical indications.

Stage IA_2 squamous carcinoma of the cervix: Difficult diagnosis and therapeutic dilemma 1406
Benjamin E. Greer, MD, David C. Figge, MD, Hisham K. Tamimi, MD, Joanna M. Cain, MD, and Roger B. Lee, MD
Seattle, Washington

The definition of stage IA_2 was tested by a retrospective review of 50 patients with early invasive squamous cell carcinoma of the cervix treated with radical surgery preceded by conization of the cervix.

Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes 1412
Miles J. Novy, MD, Janice Haymond, MD, and Mark Nichols, MD
Portland and Beaverton, Oregon

Shirodkar cerclage with perioperative tocolysis, broad-spectrum antibiotics, and indomethacin was successfully used in patients with advanced cervical changes between 21 and 26 weeks' gestation.

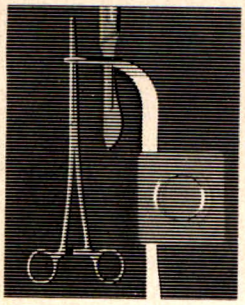
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.
NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

What is fetal distress? 1421
J. T. Parer, MD, PhD, and E. G. Livingston, MD
San Francisco, California

A consideration of the current knowledge of fetal responses to asphyxia, coupled with the known evolution of fetal heart rate patterns during asphyxia, should permit a more rational management and timing of intervention.

A comparison of the morbidity of midforceps and cesarean delivery 1428
Richard A. Bashore, MD, William H. Phillips, Jr., MD, and Charles R. Brinkman III, MD
Los Angeles, California

Midforceps delivery in selected cases is safe for the neonate and mother.

Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries 1436
Patricia A. Robertson, MD, Russell K. Laros, Jr., MD, and Rei-Ling Zhao, MD
San Francisco, California

Neonatal morbidity increased significantly in association with midforceps matched with cesarean sections in this retrospective study of term singleton pregnancies.

The placenta in the litigation process 1445
Kurt Benirschke, MD
San Diego, California

An examination of the placenta is essential for complicated births; its value in cases that come to litigation is reviewed.

Hysterectomy: A medical-legal perspective, 1975 to 1985 1451
John M. Whitelaw, MD
Sacramento, California

In a review of hysterectomy-related malpractice claims, it was found that the tort-based system does a poor job of separating bad outcomes from cases in which an error was made.

The efficacy of external cephalic version and its impact on the breech experience 1459
Joseph W. Hanss, Jr., MD
Phoenix, Arizona

External cephalic version near term is effective in reducing the incidence of breech presentation but has little effect on the cesarean section rate.

Diagnostic and therapeutic curettage in gestational trophoblastic disease 1465
John B. Schlaerth, MD, C. Paul Morrow, MD, and Maria Rodriguez, RN
Los Angeles, California

Elective curettage has limited diagnostic and therapeutic value and some risks in postmolar gestational trophoblastic disease.

Prenatal diagnosis of intracerebellar hemorrhage: Case report 1472
Raymond J. Jennett, MD, William J. R. Daily, MD, Theodore J. Tarby, MD, and Kim H. Manwaring, MD
Phoenix, Arizona

Intracerebellar hemorrhage, which is commonly attributed to intrapartum traumatic events, was diagnosed by antepartum ultrasonographic examination.

Myomectomy as a reproductive procedure 1476
Donald C. Smith, MD, and Jane K. Uhlir, MD
Seattle, Washington

Myomectomy was successfully performed in 64 consecutive patients with large uterine myomas who wished to preserve childbearing potential.

Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting 1483
Sheila J. DiMarzo, PhD, Janet Huang, MD, Joseph F. Kennedy, MD, Benito Villanueva, MD, Stephen A. Hebert, MD, and Philip E. Young, MD
San Diego, California

The probability of pregnancy after a seven-cycle trial of artificial insemination by donor is similar with fresh or cryopreserved semen, although monthly fecundability is higher with fresh semen.

The computerized digital imaging colposcope: Future directions 1491
William E. Crisp, MD, Brian L. Craine, MD, PhD, and Eric A. Craine, PhD
Phoenix and Tucson, Arizona, Oakland, California, and Ft. Collins, Colorado

A new digital imaging colposcope has the capacity to introduce optically and digitally filtered and processed images of the cervix for research and clinical applications.

TRANSACTIONS OF THE FIFTY-SEVENTH ANNUAL MEETING OF THE CENTRAL ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Men without chests 1499
James H. Maxwell, MD
Colorado Springs, Colorado

A prospective controlled study of outcome after trauma during pregnancy 1502
Mark D. Pearlman, MD, Judith E. Tintinalli, MD, and Robert P. Lorenz, MD
Royal Oak and Detroit, Michigan

The complications of trauma during pregnancy are often predictable and include frequent fetomaternal transfusion, abruptio placentae, and preterm uterine contractions.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Richmond — Small, congenial clinic setting staffed by five physicians and five nurse practitioners with ready consultation for other services, including perinatology. Practice general OB/GYN, high-risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser welcome. Resident teaching opportunities exist. Staff call at Kaiser Hospital in Oakland, shared with resident staff.

Oakland — Twenty physicians, 12 residents offer services in oncology, infertility, maternal-fetal medicine and a large ICN.

Redwood City — Specializes in family-centered maternity care; offers modern LDR rooms and full range of gynecological surgery. With ten physicians, 24-hour call is required three times each month. Beautiful Peninsula location, near San Francisco and the Pacific Ocean.

Stockton — Small four physician department in a new clinic building with new equipment, including laser. Stockton's lifestyle is affordable and attractive, offering recreational activities such as boating on the inland waterways. Centrally located, with mountains to the east and San Francisco Bay Area to the west.

Roseville — Eight physicians and two nurse practitioners in clinic setting. Patients are hospitalized for delivery and surgery in Sacramento where physicians take call for L&D and emergency about 5 times each month.

San Francisco — Full range of services including large high-risk, tertiary care OB service. Eighteen physicians, including GYN Oncologist. Residency program. Clinical research and academic teaching appointments available.

Sacramento — Growing metropolitan area between San Francisco Bay Area and Sierra Nevada mountains. Up-to-date facility with active staff of 14 and excellent residency program affiliated with the University of California at Davis. Flexible call averaging five shifts per month covers L&D, emergency room and inpatient services.

Pleasanton — Staffed by four physicians and three nurse practitioners, clinic provides general OB/GYN services, non-stress tests, ultrasound and cystoscopy. Consultant support, including a Perinatologist, readily available. Share call with staff of Walnut Creek Medical Center. Affiliated with the University of California at San Francisco as clinical instructors.

Fresno — Ground-floor opportunities in growing area for clinically-oriented individuals. Provide general OB/GYN; special interests encouraged. Planning new $26 million outpatient facility to accompany current medical office building. On call every fourth night and weekend. Local residency program at Valley Medical Center affiliated with the University of California at San Francisco. Teaching positions possible.

South San Francisco — Full service except L&D. Nine physicians, six nurse practitioners. On San Francisco Peninsula, 15 minutes from downtown.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. For complete information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, Dept. AOG-8348, 1814 Franklin, 4th Floor, Oakland, CA 94612. Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—Preliminary data 1511
Jyothi Raman, MS, Dipali V. Apte, BS, M. Joan Dawson, PhD, Stanley J. Bobowski, MD, and Suzanne R. Trupin, MD
Urbana-Champaign, Illinois

Magnetic resonance spectroscopy may reveal biochemical abnormalities in histologically normal biopsy specimens.

The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: A prospective blinded study 1518
Dev Maulik, MD, PhD, Prasad Yarlagadda, PhD, James P. Youngblood, MD, and Pamela Ciston, RDMS
Kansas City, Missouri

Umbilical arterial systolic/diastolic ratio performed at 34 to 36 weeks of pregnancy can predict an adverse perinatal outcome.

Surgical management of breast disease in an obstetrics and gynecology group 1526
James A. Hall, MD, Bernard R. Hall, MD, Duffy C. Murphy, MD, and Kyle A. Hall, RN, MSN
Logansport, Indiana

The surgical management of benign and malignant breast disease by a group of obstetricians and gynecologists from 1978 through 1988 is reviewed.

Evaluation of a continuous combined low-dose regimen of estrogen-progestin for treatment of the menopausal patient 1534
Louis Weinstein, MD, Chhanda Bewtra, MB, BS, and J. Chris Gallagher, MD
Tucson, Arizona, and Omaha, Nebraska

Favorable changes in lipoprotein profiles, endometrial histologic features, and bleeding patterns are demonstrated by using a continuous low-dose regimen of estrogen-progestin.

Ultrasonography and external cephalic version at term 1542
William L. Donald, MD, and John J. Barton, MD
Chicago, Illinois

Ultrasonography is useful in the evaluation of patients with a nonvertex presentation at term and can be used to predict which patients are likely to have a successful external cephalic version.

Cordocentesis for rapid karyotyping 1548
Dinesh M. Shah, MD, Periclis Roussis, MD, Janet Ulm, MSSW, Phillipe Jeanty, MD, and Frank H. Boehm, MD
Nashville, Tennessee

Rapid fetal karyotype obtained from cordocentesis samples revealed chromosomal abnormalities in 11.9% of cases studied, occurring primarily in fetuses with previously identified complications.

The effect of prolactin on murine in vitro fertilization and embryo development 1553
William G. Dodds, MD, Jeffrey Fowler, MD, Amy Peykoff, BS, Kurt F. Miller, PhD, Chad I. Friedman, MD, and Moon H. Kim, MD
Columbus, Ohio

Purified mouse prolactin at physiologic to supraphysiologic levels demonstrated no effect on mouse in vitro fertilization or embryo development.

The prevalence of substance abuse in patients with suspected preterm labor 1562
Judith A. Ney, MD, Sharon L. Dooley, MD, Louis G. Keith, MD, Ira J. Chasnoff, MD, and Michael L. Socol, MD
Chicago, Illinois

Twenty-four of 141 (17%) patients admitted in suspected preterm labor were found to have urine toxicology screens that were positive for substance abuse.

Selective termination: Clinical experience and residual risks 1568
Mark I. Evans, MD, Marlene May, RDMS, Arie Drugan, MD, John C. Fletcher, PhD, Mark P. Johnson, MD, and Robert J. Sokol, MD
Detroit, Michigan, and Charlottesville, Virginia

Selective termination is a technically feasible and ethically acceptable procedure to offer to patients with multifetal gestations.

Spontaneous cell death in the chorion laeve 1576
Tim H. Parmley, MD
Little Rock, Arkansas

Histologically, trophoblastic cell death in the near-term chorion is similar to that of those cell populations whose synchronous deaths "time" various developmental events.

Flow cytometric evaluation of epithelial ovarian cancer 1584
Vanessa M. Barnabei, MD, PhD, David Scott Miller, MD, Kenneth D. Bauer, PhD, Tariq M. Murad, MD, Alfred W. Rademaker, PhD, and John R. Lurain, MD
Chicago, Illinois

Tumor specimens from 115 patients with epithelial ovarian cancer were evaluated by flow cytometry; these findings were compared with traditional prognostic parameters by univariate and multivariate analysis and showed that S-phase fraction is a useful prognosticator.

The Green Bay cesarean section study. I. The physician factor as a determinant of cesarean birth rates 1593
Robert K. DeMott, MD, and Herbert F. Sandmire, MD
Green Bay, Wisconsin

Higher cesarean birth rates resulting from the individual practice style of the physician do not result in improved neonatal outcomes.

Contents

Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance 1603
Robert P. Lorenz, MD, Christine H. Comstock, MD, Sidney F. Bottoms, MD, and Sharon R. Marx, RNC, MS
Royal Oak and Detroit, Michigan

In this prospective randomized study of methods of cervical assessment in patients at risk for preterm birth, ultrasonography and bimanual examination had similar effectiveness.

Sacrospinous ligament fixation at the time of transvaginal hysterectomy 1611
Stephen H. Cruikshank, MD, and Donald W. Cox, MD
Minneapolis, Minnesota, and Morgantown, West Virginia

Sacrospinous ligament fixation of the vagina was performed with minimal morbidity as an adjunct procedure in those patients lacking adequate pelvic support at the time of transvaginal hysterectomy.

Reproductive performance after methotrexate treatment of ectopic pregnancy 1620
Thomas G. Stovall, MD, Frank W. Ling, MD, and John E. Buster, MD
Memphis, Tennessee

Pregnancy rates after methotrexate treatment of ectopic pregnancy are better than those achieved by traditional surgical methods and comparable to those with laparoscopic salpingostomy.

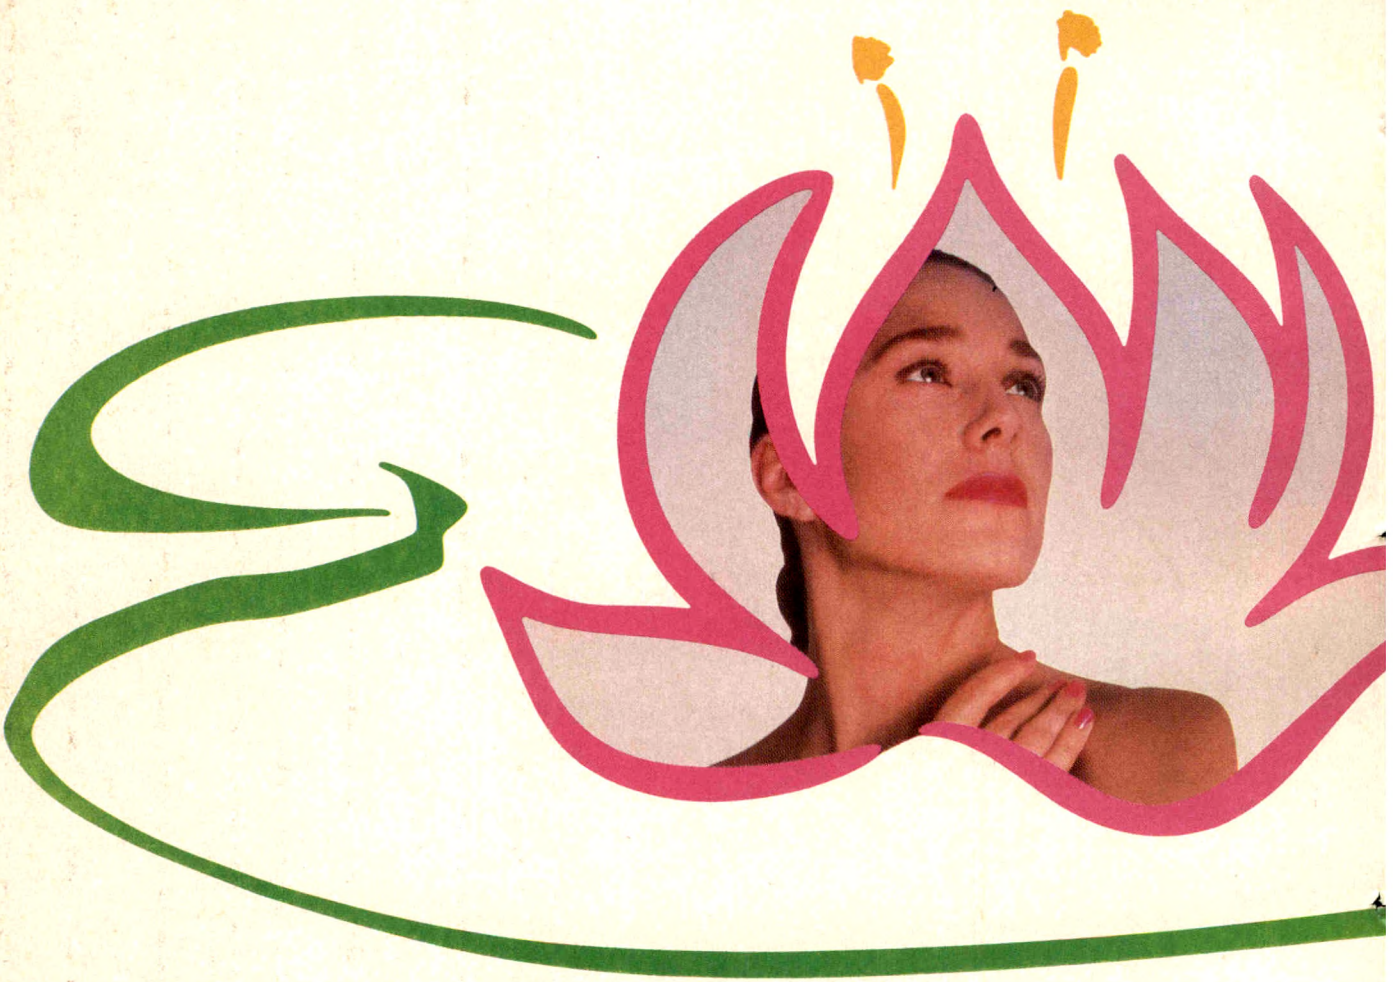
Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*



Contact Mosby-Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 7394. In the U.S., call toll-free: 1-800-325-4177, ext. 7394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

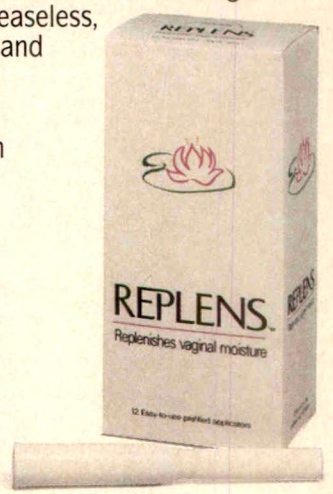
Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by Mosby-Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/90 $00.00 + .10.

Moisture that lasts and lasts

The only proven vaginal moisturizer

Bioadhesive technology clinically proven to end vaginal dryness

Statistically significant results from a multicenter clinical trial have shown that REPLENS increases moisture and improves epithelial integrity.* Through unique bioadhesive technology, REPLENS provides ongoing hydration of underlying vaginal tissue to end discomfort and painful intercourse.



Nonhormonal relief for more than 25 million women

Although most prevalent during menopause, vaginal dryness can occur during many stages of a woman's life. All these patients will appreciate your recommendation of REPLENS. REPLENS is a very natural way to bring back a feeling of youth and confidence many women thought they had lost forever.

Three times a week for full-time comfort

REPLENS relieves vaginal dryness, discomfort, and painful intercourse for up to 72 hours with a single application. REPLENS is greaseless, odorless, and nonirritating and packaged in disposable applicators for ease of use.

Call toll-free for information 1-800-749-1919.

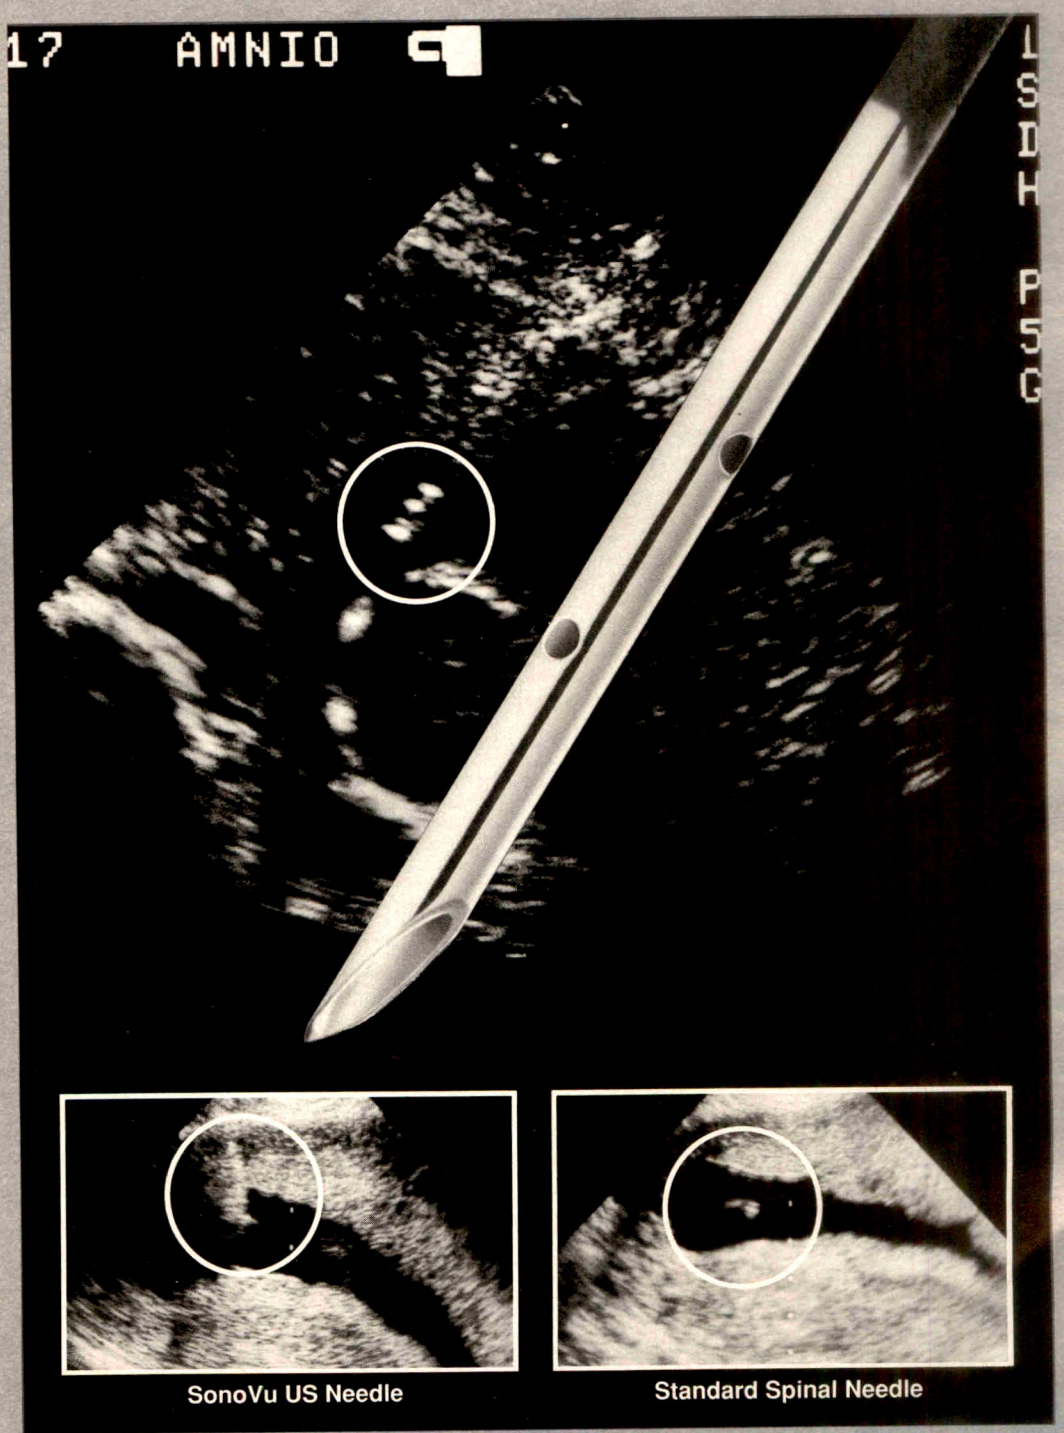
SonoVu U™—A visible im-rovement in ultrasound-guided aspiration.



The clearly visible bright echoes on the real-time sonogram below mark a breakthrough in accuracy and safety for fine-needle aspiration under ultrasound guidance.

SonoVu US, from E-Z-EM, is the first in a family of procedural needles designed specifically for enhanced ultrasound visualization.

Precisely formed 0.44 mm distal side holes on the cannula closely match the wavelength of ultrasound generated by a 3.5 MHz transducer. Uniform diffraction of the wave at each hole creates a highly visible echo on the US display.

The side holes also provide a significant increase in needle flow rate, and ensure free flow should the tip become occluded—often the case with spinal or chiba needles.

Developed for use in amniocentesis, the SonoVu design can offer similar benefits in such procedures as US-monitored biopsy and cyst aspiration. For more information on 20- and 22-gauge SonoVu US needles from E-Z-EM, call 1-800-544-4624.

For both the patient and the practitioner, E-Z-EM products set the standards for convenience, safety, and quality in:

- GI Radiology
- Interventional Radiology
- CT Scanning
- Ultrasound
- Magnetic Resonance Imaging
- Angiography
- CEA Immunostaining
- Radiation Oncology
- Patient Prepping
- Protective Products
- Computerized Information Management Systems

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from Mosby-Year Book, Inc., or the Editors on request.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or

accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

TRI - NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

BRIEF SUMMARY

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 yellow-green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 7 inert orange tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg
ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications: Prevention of pregnancy.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions:
- Thrombophlebitis or thromboembolic disorders
- A past history of deep vein thrombophlebitis or thromboembolic disorders
- Cerebral vascular or coronary artery disease
- Known or suspected carcinoma of the breast
- Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia
- Undiagnosed abnormal genital bleeding
- Cholestatic jaundice of pregnancy or jaundice with prior pill use
- Hepatic adenomas, carcinomas or benign liver tumors
- Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial Infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS,** section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have an increase in mortality greater than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS,** sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section):

• Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed:

• Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related:

• Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted:

• Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

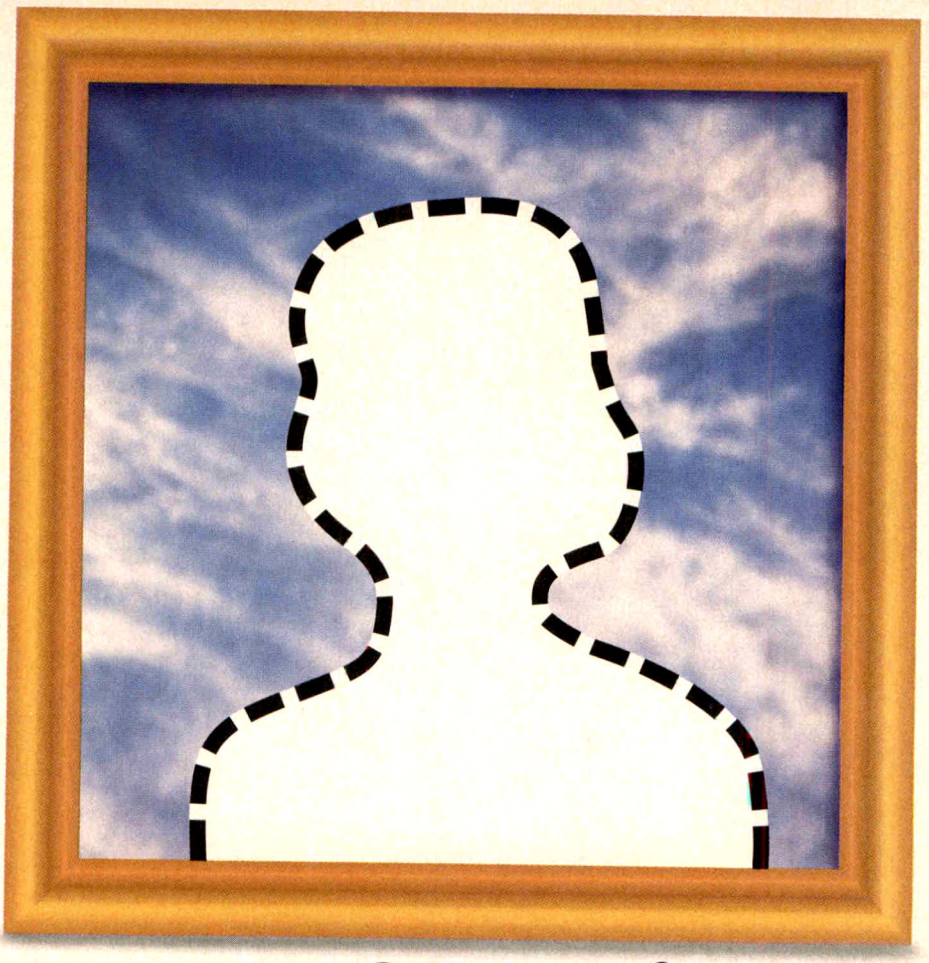
NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses:

• Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation:



• Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use:

• Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

Rev. August 1989

SYNTEX

Picture your OC patients here.

Your younger patients just starting contraception, because low impact norethindrone lowers the risk of acne and bloating.

Your career-oriented patients delaying childbearing, because reduced progestin helps avoid late cycle side effects, such as weight gain, headache, and depression.

Your older, nonsmoking patients restarting contraception, because Tri-Norinyl is the only multiphasic OC to lower progestin in the late cycle to minimize overall hormonal impact.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see adjacent page for brief summary of prescribing information. © 1990 Syntex Laboratories, Inc. 814-G2-116-89

TRANSACTIONS OF THE FIFTY-SIXTH ANNUAL MEETING OF THE PACIFIC COAST OBSTETRICAL AND GYNECOLOGICAL SOCIETY

The tyranny of technology

Presidential address

David C. Figge, MD

Seattle, Washington

Society's fascination with medical advances, and particularly with the changing technology that highlights those advances, is readily apparent. A sense of drama and expectation seems to surround them and in turn draws the interest of the media. It is this proliferation of medical technology, emerging as it does as the most visible accomplishment of our current generation in medicine, that serves as the subject for my comments today. It is a phenomenon that has dramatically altered the practice of medicine within our specialty. I propose to consider the impact of this developing technology on our society, our educational mission, and finally on the individual practice within our specialty. I will likely reveal some personal prejudices because I must confess a pervasive sense of uneasiness that has come about with my consideration of these changes.

Technology, of course, is merely the application of scientific discovery. It has been suggested that advances in medical technology over the past 20 years alone far exceed those of the previous 200 years. They differ greatly in terms of purpose. Many are diagnostic, such as multichannel chemistry panels, ultrasonography, computerized tomography, electronic fetal monitoring, and nuclear magnetic resonance. Others deal with survival—the evolution of intensive care units. Many, such as renal dialysis and cardiac pacemakers, serve to manage recognized illness. Some, such as organ transplants and joint replacements, actually effect cure and others, such as vaccines, deal with disease prevention. Each category has served to alter the profile of medicine and the impact in the field of obstetrics and gynecology has been particularly striking.

Ultrasonography developed into a medical tool early in the 1970s. The subsequent evolution of gray-scale technology allowed visualization of the internal echo textures. With the introduction of computers into the image-making process, resolution close to 1 mm became possible and enhancement with the vaginal probe allowed measurements of growth in the human follicle. It is now a routine practice to retrieve the ovum at an appropriate time for in vitro fertilization. Its use has been effective in the definition of pelvic neoplasms and in the detection of ascites, hydronephrosis, and metastatic disease. The internal composition of ovarian tumors can be predicted with confidence. Perinatologists and reproductive endocrinologists now regard the availability of ultrasonography as critical within their specialties and refer to ultrasonography as the physician's "third eye." They see it as a tool well within the province of the clinician rather than a facet of diagnostic radiology.

Computed tomography (CT) came about with the development of computer technology. Axial sections at 10 mm intervals are now available in all organ systems. In oncology it has proved particularly helpful in the definition of pelvic side wall disease and in the detection of enlarged paraaortic lymph nodes. Both ultrasonography and the CT scan have permitted accurate aspirations of cells from suspicious intraabdominal masses or nodes with guided thin-needle orientation.

Magnetic resonance imaging (MRI) closely followed other imaging techniques and has improved on our ability to detect and define intraabdominal pathologic conditions in a noninvasive approach. The leading promise is the hope of distinguishing between inflammatory and neoplastic changes.

The list of achievements is lengthy. Laparoscopy, amniocentesis for prenatal diagnosis, fetal monitoring, laser surgery, villous sampling, and measurements of tumor-specific antigens are all advances within our own time frame. Our specialty in particular has eagerly embraced these technologies and accepted them as inherent tools of clinical practice. Such advances have enhanced our clinical skills and added new dimensions in clinical diagnosis and therapy. We can point to many examples in which the patient has benefitted. It is rewarding to see a woman with an early diagnosis of ectopic pregnancy treated on an ambulatory basis with the distended tube meticulously incised and the aberrant gestation extracted under laparoscopic control. Laser photovaporization guided by the colposcope substitutes for the scalpel in the treatment of intraepithelial neoplasms of the vulva and vagina. Infertile couples may avail themselves of in vitro fertilization. Patients can frequently be managed on an ambulatory basis for disorders that previously required extended hospitalization.

Lay magazines and the popular press have been quick to applaud these new techniques. The ever-scrutinizing legal profession has been quick to recognize them as documentable criteria on which to base decisions of standards in practice. There has been an almost irresistible urge to quickly appropriate each new development into our day-to-day practice. The referring physician can point with pride to the fact that he has already obtained a sonogram and MRI on his patient with uterine cancer. Certainly he is abreast of the current technology! The pressure is compounded by the attitude of an informed public, exposed to glowing reports in the lay literature, who perceives the technology as the "cutting edge" of medicine. Any reluctance on the part of their physician to request this state-of-the-art technology may be regarded as neglect or lack of current medical update.

Like the mythical Roman god Janus, technology projects two faces. Our love affair with technology, interdigitating it into the every fabric of medical care, has also exacted a price—a price often subtle and concealed but nevertheless pervasive. The cost of our emerging technology has generally been ignored or subordinated to the enthusiasms for a new approach. Imaging studies are expensive diagnostic refinements and even ultrasonography carries a significant price tag that should at least allow us to challenge the prevailing tendency to offer it as a substitute for a bimanual pelvic examination. The expense inherent in expensive new technology not only collides with harsh economic realities but in our societal matrix of third-party payments and political expediency it may now have been permitted to grow to a point where it could very well threaten society's economic balance.

In the April 1989 *ACOG Newsletter* the Executive Director of the American College of Obstetricians and Gynecologists, Dr. Warren Pearse, drew our attention to Professor Uwe Reinhardt's observation that there are two alternatives for the regulation of medical costs.[1] Either the total number of dollars paid for medical care can be determined by society, hence allowing physicians to practice as they choose as in the case in the United Kingdom and in some health maintenance organizations *or* the dollars paid may be open ended with regulation of physician services and practice activities. It now appears that the latter option is emerging within this country and will continue if the present indifferent posture over medical costs continues to prevail. We cannot continue to have it both ways and current economics suggest that our window of opportunity is fading.

In 1950 U.S. health care expenditures were $12.7 billion and each American spent $82 per year for this purpose. In 1975 the cost had risen to $132.7 billion and represented 8.4% of our gross national product. By 1985 the figure had risen to $425 billion—10.7% of the gross national product with a per capita expense of $1721—the highest national per capita health expenditure in the world. Health care costs last year (1988) were $618 billion and recent studies project the cost at $1.9 trillion by the year 2000.[2] By 1971 health care costs had exceeded expenditures for national defense and the gap continues to increase.[3] In 33 years health care expenditures in this country as a fraction of the gross national product have more than doubled. A total of 10% of the cost of each medium-sized car goes to pay for health care benefits. Every family must now "tithe" more than 10% of its income to pay for our health care system.[4]

Unlike most economic models, the cost of health care expands without any visible braking mechanism. The consumer and provider both perceive biomedical technologies as desirable and press for their inclusion. These views have been skillfully reinforced by the biomedical science establishment and medical technology industries. With the use of just a few of the most recently developed medical interventions for each individual in our society where it could be indicated could easily absorb the entire gross national product. The costs are eminently justifiable and defensible. Whether they are necessary or even appropriate is a far more difficult question but one that we must inevitably face.

A generous and permissive society accepts and em-

braces these costs as long as they are distributed to all subscribers and are not visibly attached to increased taxes. How long can this compassionate society support the escalating cost of medical care when this cost competes with education, care for the indigent and homeless, and social programs that have become a fixture in our culture? End-stage renal disease benefits, which include both dialysis and transplants, were embraced by our legislative respresentatives some years back. The estimated cost of this isolated, single gesture of generosity will reach $6.3 billion in 1992.[2] Our society's social values have changed over the past 100 years from a personalized approach dependent on individual initiative to a current philosophy that states that health care is a right and that the federal government must see to it that everyone enjoys that right to the fullest degree possible. Future developments are glaringly apparent. Five states now require insurance companies to cover infertility treatment including in vitro fertilization. Last year (1988) the average cost of diagnostic and medical treatments for infertility was more than $2500 per couple and if in vitro fertilization were involved the median cost for each attempt at conception was $5000 to $6000. At the present time only about 10% to 15% of women undergoing the procedure once may expect to have a successful pregnancy. A current effort is being made to introduce into congress legislation that would mandate full infertility coverage in the health insurance packages offered to 3 million government workers. The sponsor of this measure (Representative Pat Schroeder, Democrat of Colorado) has asserted "reproductive organs are a very important part of your bodily function. If they don't appear to be functioning, they ought to be covered by your health insurance." The proposal mandates that health plans cover "family building activities" and these are defined in the legislation as "medical procedures necessary to overcome infertility so as to achieve pregnancy and to carry it to term, and necessary expenses related to the adoption of a child."

To what degree has the blossoming of medical technology contributed to escalation in the costs of the health care system? In any such consideration technology must be interpreted broadly rather than focusing only on isolated examples that can be identified as cost effective. Medical technology is said to have accounted for 15% to 25% of the increased cost of hospital care over the past decade. However, if adjustments are made for systemic general inflation then within the real growth category medical technology accounts for 60% to 70% of the increase![3] New technologies have provided more efficient and accurate means to diagnose or exclude disease, but generally only achieve palliation rather than cure. Health care specialists for the most part concede the influence of technology. The President's Biomedical Research Panel concluded that ". . . new health care technology is a major cause of the large yearly increases in national health expenditures."[5] Not only has the proliferation of expensive instrumentation been an issue but the people required to run the equipment and deliver the services also become more numerous, specialized, and expensive.

The impact of technology on medical education offers another paradox that is unsettling in many respects. The student learns that the services to be given involve a great deal of scientific technology and eventually mastery of the technology becomes the student's preeminent aim in contrast to the traditional personalized involvement. Technology will always eventually win out over the more humanistic approach in medicine. After embracing the skills of technology, the abandonment of traditional "hands on" care frequently follows. In a final examination this year a student was asked how to diagnose a breech presentation and position. The immediate response was ultrasonography. That student was completely unfamiliar with and frankly rather disinterested in the classic maneuvers of Leopold. Inasmuch as the technology has become so overwhelming and the specialization so fragmented for the patient, we must now rely on others to focus on the patient as a total personal entity. These professionals—family practitioners, physician assistants, nurse practitioners—are attempting to repersonalize a health care system that has become so involved in abstract impersonal technology that it has often lost sight of the total patient it is supposed to serve.

I would suggest that the physician today must, for the first time, accept a second role in the pursuit of his specialty. He must act not only as a practitioner concerned with the health and care of his patient but also as a uniquely informed member of a society faced with spiraling health care costs and the need to make informed decisions about the use and role of technology as it develops within the spectrum of health care services. He is part of this larger society that depends on his decisions and his interpretation of the place and critical need for the technologic advances that are developing. He must do this in a prudent and conscientious philosophy that transcends ego support and defensive mechanisms.

Physician concerns over cost containment and a thrust toward a more prudent approach to the advent of technology have yet to seriously emerge. A rather indifferent attitude toward any process of selectivity seems to be the general rule. After listening to a litany of two ultrasonographic examinations and a CT scan that preceded an operation for a dermoid cyst, one of our senior faculty grumbled that the added expense to this patient multiplied so many times over in our com-

munity would go a long way toward solution of the problem of the homeless in Seattle! The physician who will search carefully for a service station that sells gasoline for a few pennies less will casually order a $250 ultrasonographic examination without a second thought.

It has become almost a reflex reaction in many medical communities to request an ultrasonographic study or CT scan to confirm a clearly palpable adnexal mass. There are circumstances in which this may be appropriate but when the findings on examination clearly require and justify surgical exploration the value of the study is questionable. The character of the sonogram may lead the physician to suspect either a benign or malignant neoplasm but clearly surgical exploration is required. The value of the study, then, primarily is to the physician in clarification of his role and support of his decision. The value to the patient remains speculative.

We have enthusiastically applauded the value of electronic fetal monitoring, which is currently used in roughly one half of obstetric cases at an annual cost of $400 million, and some now recommend its use in every delivery.[2] There is little evidence that it has had an effect on fetal outcome assessed by current statistics. A National Institutes of Health consensus conference concluded that there was no evidence that routine ultrasonographic examination in every pregnancy would improve pregnancy outcomes. Yet our fascination and enthusiasm for this procedure has even prompted a highly respected authority in our field to argue for its inclusion in the management of every pregnancy—if only to "help parents bond with their baby." His arguments may seem appropriate but again certainly fail to effectively address the quandry of cost effectiveness.[6]

The tendency to insert new technology into proved conventional approaches to diagnosis seems almost irresistible. In a review of case lists of applicants for American Board examinations some candidates routinely examined every patient with abnormal uterine bleeding with hysteroscopy before curettage, despite the additional cost and the acknowledged reality that the added exercise would seldom prove of benefit.

Intrigued by the obvious question, we carried out a rather interesting study within our department. The medical records of 112 consecutive patients referred over a 4-month interval for treatment of gynecologic malignancy were reviewed. The only study requirement was that the referred patient have some form of prior diagnostic imaging—ultrasonography, CT scan or MRI—and that surgery be performed within 8 weeks of that imaging. A retrospective review of the 40 patients who qualified determined that the radiologic diagnostic accuracy when compared with the surgical findings was only 52% and that in only five of the 40 cases did these adjuvant diagnostic imaging studies contribute information that actually modified or changed the clinical management! In another pilot study from our institution we were interested in the evaluation of the additive value of MRI imaging in cervical malignancy. This study showed that among a small series of patients undergoing radical surgery for cervical cancer, MRI imaging was actually less accurate than clinical examination in estimating the extent of disease defined by the final surgical pathology, yet this practice has already become routine in some centers.

Some form of internal audit must be developed to objectively evaluate and control the use of our expanding technology among our professional community. Third-party payers will not indefinitely provide us with unlimited financial access to expensive technology without a demonstrable savings in return. We will indeed be called to task by cost accounting segments of our society who are unmoved by emotional arguments. The public cries out for an increasing use of technology under the impression that it saves lives and improves medical care. When this can be shown, its selective introduction into the profile of medical care should be welcomed. Perhaps the bottom line of our judgment must rest with the traditional yardstick "has this procedure changed or improved the management in this specific patient." Too frequently it merely serves to reassure the physician, to bypass traditional approaches that will yield the same result, or to document observations that have already clearly defined the approach to treatment.

Technologic advances have enormous potential and their development must be encouraged. Yet our eagerness to precipitously embrace them, ignoring their imperfections and disdaining criteria for suitability, stands out in sharp contrast with the tradition of analytic reasoning so firmly established in other professional decisions we make in the practice of medicine. Because they represent new approaches that capture the imagination we have rushed to introduce it into practice without caution and discrimination.

Medical technology has indeed emerged as a form of tyranny—a complex and often attractive form of tyranny indeed—but nevertheless a symbol of what may be a decisive factor in the determination of whether medical practice as we know it survives. The issue at stake is more than merely cost accounting. It also involves an element of intellectual and ethical honesty. I plead not for a disregard of this technology but only for its selective and judicious inclusion mindful of the significant impact it may well have on the structure of our society and our medical practice. We are part of a larger society that must now face agonizing decisions that involve the expanding subsidy for health care. We have continually sidestepped any responsibility for crit-

ical decisions with regard to the appropriate role for our developing medical technology. Somewhere the first steps must be taken. I would submit that the responsibility may well rest on the guidance of distinguished professional societies such as the one you and I enjoy.

Prophylactic intrapartum amnioinfusion: A randomized clinical trial

Thomas H. Strong, Jr., MD, Gretchen Hetzler, MD, Albert P. Sarno, MD, MAJ, USA, and Richard H. Paul, MD

Los Angeles, California

Amnioinfusion was performed in a prospective, randomized trial of 60 women in the latent phase of labor with oligohydramnios, as defined by an amniotic fluid index ≤5.0 cm. All fetuses were at least 37 weeks' gestational age, had normal baseline fetal heart rate variability, and no clinically significant fetal heart rate decelerations at the outset. Subjects in the amnioinfusion group (n = 30) were titrated to and maintained at an amniotic fluid index level ≥8.0 cm throughout labor. In the group receiving amnioinfusion, significantly lower rates of meconium passage (p = 0.04), severe variable decelerations (p = 0.04), end-stage bradycardia (p = 0.05), and operative delivery for fetal distress (p = 0.002) occurred. Significantly higher umbilical arterial blood pH values were also noted in the infusion group (p = 0.02). We conclude that prophylactic intrapartum amnioinfusion is an important technique for the reduction of intrapartum morbidity. (Am J Obstet Gynecol 1990;162:1370-5.)

Key words: Amnioinfusion, amniotic fluid index, fetal distress

Amniotic fluid has many important functions during pregnancy, including protection of the umbilical cord from compression. In rhesus monkey preparations, it has been shown that removal of amniotic fluid results in variable decelerations in the fetal heart rate (FHR) that resolve when the lost fluid volume is replaced.[1] The inverse relationship between amniotic fluid volume and FHR decelerations has been confirmed in humans by Rutherford et al.[2] Therefore it is reasonable to assume that cord compression, as evidenced by variable decelerations, will be more frequent with decreased amniotic fluid volume. Clinically, oligohydramnios can occur in postdates pregnancies, intrauterine growth retardation, fetal anomalies, or spontaneous rupture of the membranes.

Transvaginal infusion of saline solution into the amniotic cavity (amnioinfusion) can ameliorate variable decelerations of the FHR during labor. Miyazaki and Nevarez[3] found that amnioinfusion led to complete resolution of repetitive variable FHR decelerations in 51% versus 4.2% in control subjects. Nageotte et al.[4] noted significantly fewer variable decelerations in women with preterm premature rupture of fetal membranes who received prophylactic intrapartum amnioinfusion. The group that did not have amnioinfusion was also noted to have a higher cesarean delivery rate for fetal distress. More recently, Wenstrom and Parsons[5] noted a lower rate of meconium aspiration among women who had amnioinfusion and who had thick meconium during labor.

Sarno et al.[6] evaluated the amniotic fluid volume in laboring women using the amniotic fluid index.[7] A significantly increased rate of cesarean delivery for fetal distress and 1-minute Apgar scores less than 7 were associated with an amniotic fluid index value in early labor of ≤5 cm. In addition, decreased FHR variability, severe variable decelerations, and prolonged FHR decelerations were more common with decreased amniotic fluid index.

Despite the efficacy of amnioinfusion in the treatment of variable decelerations, 10 to 25 minutes is usually required before a "therapeutic" volume is instilled by means of gravity flow. This may preclude the technique when rapid intervention is warranted. We hypothesize that a more optimal time for amnioinfusion among those at risk for intrapartum morbidity is before the occurrence of significant FHR abnormalities or the passage of meconium. The purpose of this study was to determine the efficacy of prophylactic intrapartum amnioinfusion in term gestation (≥37 weeks) with amniotic fluid index values ≤5 cm.

Material and methods

During the 6 months from Oct. 1, 1988, through March 31, 1989, laboring women with oligohydram-

nios (amniotic fluid index ≤5 cm) at Los Angeles County/University of Southern California Women's Hospital were evaluated for participation in the study. Criteria for entry included singleton gestation, vertex presentation, ≤4 cm of cervical dilation, ≥37 weeks' gestation, normal baseline FHR variability, and estimated fetal weight >2500 gm. Patients were excluded for any of the following reasons: late decelerations, moderate or severe variable decelerations, vaginal bleeding, chorioamnionitis, meconium-stained amniotic fluid, fetal anomalies, or uterine anomalies. All subjects participating in the Institutional Review Board–approved study were enrolled with written, informed consent. Consenting women were placed in one of two groups according to a table of random numbers, the randomized permuted block technique ($n = 6$), and opaque, sealed envelopes. The two groups consisted of those with an amniotic fluid index ≤5 cm but receiving no amnioinfusion (controls) and those with an amniotic fluid index ≤5 cm who received prophylactic amnioinfusion.

Amnioinfusion was accomplished in the manner outlined by Miyazaki and Nevarez[3]; 250 ml of normal saline solution warmed to 37° C, was infused through an intrauterine pressure catheter at a rate of 10 to 20 ml/min. Infusions of 250 ml were repeated until an amniotic fluid index of at least 8 cm was reached. External uterine tokodynamometry was used during the actual infusion process. Patients receiving infusions underwent hourly amniotic fluid index determinations, and repeat amnioinfusion was performed whenever the amniotic fluid index fell below 8 cm.

With a value of $p = 0.05$ used to establish statistical significance and assuming a β-error of 0.2, a calculation of power for the study suggested that a minimum of 30 subjects be assigned to each study group. The power calculation was based on the differential cesarean delivery rates for fetal distress in the infusion versus control groups of Miyazaki and Nevarez[3] (14.8% versus 47.6%, respectively).

The FHR tracings in the last 40 minutes before delivery were evaluated in terms of baseline heart rate, reactivity, beat-to-beat variability, and the presence of variable or late decelerations. Variable decelerations were graded as mild, moderate, or severe according to the criteria of Kubli et al.[8] Fetal heart rate reactivity was considered present if a single acceleration of the FHR of 15 beats/min from baseline persisting for 15 seconds or more was noted. Intrapartum decelerations were considered significant only if noted with 50% or more of contractions. All heart rate strips were evaluated by the same examiner (A. S.), who was unaware if the patient received amnioinfusion. Statistical comparisons were performed with Student's t test, χ^2, or Fisher's exact test.

Results

Informed consent was obtained for 60 patients who met the inclusion criteria for the study. No eligible study candidate refused to participate. Thirty subjects were randomized into each group. The treatment and control groups were similar for maternal age, parity, gestational age, and amniotic fluid index (Table I). In addition, the groups had statistically similar proportions of nulliparous women, postdates pregnancies (estimated gestational age ≥ 41 weeks), and patients with intact membranes at the time of admission to labor and delivery. However, the interval from membrane rupture to delivery was significantly longer ($p = 0.01$) in the infusion group.

The infusion group required an average of 1.6 ± 0.3 infusion sequences to attain an amniotic fluid index value ≥8.0 cm. The total infusion volumes of normal saline solution required ranged from 250 to 1000 ml (mean, 379 ± 141 ml; Table II). There was no significant difference between nulliparous and multiparous women in terms of infusion volumes required. Four of 30 women (13%) required reinfusion during labor, probably as a result of fluid loss as evidenced by a decrease in the amniotic fluid index below 8.0 cm. Two women (7%) initially failed to attain amniotic fluid index values of 8 cm after amnioinfusion. There was notable vaginal leakage during the infusion process. After engagement of the fetal head, one of these subjects later received successful infusion.

One woman in the infusion group experienced an umbilical cord prolapse during a midpelvic forceps rotation attempt for a persistent occiput transverse position. An unremitting bradycardia ensued and a depressed infant was delivered by cesarean section. Until the forceps trial, the intrapartum fetal tracing had average baseline fetal heart rate variability and sporadic mild variable decelerations.

Intrapartum the amnioinfusion group had significantly less frequent meconium passage ($p = 0.04$), end-stage bradycardia ($p = 0.01$), and operative deliveries for fetal distress ($p = 0.002$) (Tables III to V). When corrected for the single patient in which the amnioinfusion failed, the infusion group had significantly fewer severe variable decelerations than control subjects ($p = 0.04$). At delivery the mean umbilical arterial blood pH value in the infusion group (7.29 ± 0.03) was significantly higher than that of the control group (7.23 ± 0.09) ($p = 0.02$). No neonate sampled in the infusion group ($n = 17$) had an umbilical arterial blood pH <7.20, whereas 28% of the arterial pH values sampled in the control group ($n = 18$) were less than 7.20 ($p = 0.015$, Fisher's exact test).

Comment

Variable decelerations of the fetal heart rate are probably caused by umbilical cord compression.[9, 10] Such

compression quite logically will be more frequent when the amniotic fluid volume is diminished. The probable benefit of amnioinfusion relates to restoration of the intrauterine fluid volume, which minimizes umbilical cord compression.

Maintenance of an adequate amniotic fluid volume provides protective cushioning of the umbilical cord during labor. On the basis of our preliminary experience, amnioinfusate that is not retained in utero provides little benefit other than the effect of lavage. Hourly intrapartum amniotic fluid index assessment is a labor-intensive process that our preliminary experience suggests may be unnecessary. Study subjects who had leakage of significant volumes of fluid usually did so during the initial infusion. After an adequate amniotic fluid index was attained in our subjects, the tendency (in 87% of women who had infusion) was for the fluid to remain in the intraamniotic space. Presumably, the fetal head well applied to the cervix serves to impede egress of fluid from the uterus.

Patients with oligohydramnios (amniotic fluid index ≤ 5.0 cm) as a result of ruptured fetal membranes probably represent a group clinically different from the patients with oligohydramnios with intact fetal membranes. Placental insufficiency, as manifested by intrauterine growth retardation or the presence of late FHR decelerations, might have theoretically played a role in the development of FHR changes among our subjects. To control for this possibility, we excluded fetuses with ultrasonographic weight estimates <2500 gm (i.e., fetuses with intrauterine growth retardation). None of the "fetal distress" diagnosed in either group was on the basis of late decelerations. Moreover, the infusion and control groups had statistically similar proportions of patients with intact membranes at admission, and the mean neonatal birth weights in both groups were similar. Therefore we conclude that both the infusion and control groups were similar with regard to the pathophysiology of oligohydramnios and subsequent FHR changes.

An amniotic fluid index ≥8.0 cm was chosen as a postinfusion goal because it was above the 5.0 cm "at risk" level and was well beyond the quoted range of measurement error (±1 cm).[11] However, an amniotic fluid index value of 8.0 cm is still significantly less (1 SD) than the mean amniotic fluid index for third-trimester gestations.[6] The mean volume infused in our study (379 ml) differed from that of Nageotte et al.[4] (1160 ml). Perhaps amnioinfusion of larger volumes would have resulted in more significant differences in the outcomes between our study and control groups. We hope further to clarify this issue with an ongoing clinical trial of prophylactic amnioinfusion at our institution.

The overall rate of nuchal cords in our study population, 25% (15/60), is in agreement with quoted rates.[12] Nuchal cords did not occur significantly more frequently in either group. However, twice as many nuchal cords occurred in the infusion group, lending further credence to the protective effect of adequate amniotic fluid volume during labor. Miyazaki and Taylor[13] noted complete resolution of variable decelerations in 10 of 11 women with nuchal cords. Thus maintenance of an adequate amniotic fluid volume through amnioinfusion may prove to be of benefit in preventing or reducing the occurrence of worrisome variable or prolonged FHR decelerations that often lead to intervention with this common problem.

Umbilical cord prolapse can occur during midpelvic forceps procedures. Therefore we believe that the cord prolapse in this study occurred as a result of the at-

tempted midpelvic forceps rotation rather than amnioinfusion. Miyazaki and Nevarez[3] also noted a single case of cord prolapse and estimate a prolapse rate of 1 per 400 (0.25%) amnioinfusion patients.[14] This rate compares favorably with the quoted rate of one in 200 (0.5%) among noninfused pregnancies in vertex presentation.[14]

Forceps procedures are done with relative frequency at our institution. For example, seven forceps deliveries were performed for fetal distress in the control group of this study, four of which were midpelvic rotations. Had midpelvic operative procedures not been performed, we suspect that the number of emergency cesarean deliveries for fetal distress in the control group would have increased to at least eight (27%) versus one (3%) in the infusion group ($p = 0.025$, Fisher's exact test).

With regard to operative delivery for fetal distress, we noted that two women from the control group who ultimately were delivered vaginally were taken to the operating room for possible cesarean delivery for prolonged FHR decelerations during the first stage of labor. In both cases, the FHRs were noted to have recovered in the operating room. Therefore both women were allowed to continue in labor. One patient received a single intravenous dose of terbutaline (0.25 mg) during the fetal bradycardia, whereas the other recovered spontaneously. The second woman was taken a second time to the operating room for fetal bradycardia that also relented. We suspect that in many facilities both women might have undergone cesarean delivery.

Intrapartum febrile morbidity (temperature ≥ 100.4° F or 38.0° C) did not occur significantly more frequently in the infused group, although a trend is present (Table III). It is not likely that the intrapartum temperature elevations were directly caused by the amnioinfusion procedure itself. Rather, we suspect that the increased rate of intrapartum febrile morbidity was related to the significantly longer labors. In addition, women in the infusion group were subject to significantly longer periods with ruptured membranes, more pelvic examinations, and longer periods of internal monitoring. Curiously, even when comparing only women who were delivered vaginally, the infu-

sion group still had significantly longer rupture of membranes-to-delivery intervals ($p < 0.01$). Neither Nageotte et al.[4] nor Wenstrom and Parsons[5] have noted significant differences in terms of length of labor or febrile morbidity. Currently we cannot explain why those in our infusion group had longer labors.

In summary, this study has shown that laboring women at or beyond term with oligohydramnios apparently benefit from prophylactic amnioinfusion. The procedure of amnioinfusion is simple, safe, low-cost, and significantly reduces the incidence of intrapartum morbidity. Further expanded evaluations should be undertaken to clarify the indications, application, and efficacy of this technique. Limited careful use of amnioinfusion does not seem unreasonable based on our current understanding, but caution should be used before widespread application of this intervention is contemplated.

Discussion

DR. ROBERT GOODLIN, Denver, Colorado. Dr. Strong, Althabe et al.[1] described the same sort of response in the 1950s and 1960s. They related the incidence of fetal distress and the length of labor to amniotic fluid volume as you have done. However, they stated that the vagal heart rate changes were a result of head compression, which makes more sense to me than cord compression. In your ultrasonographic examinations, have you any evidence that cord compression is really relieved with amnioinfusion?

REFERENCE

DR. JULIAN PARER, San Francisco, California. I would like to expand on Dr. Goodlin's question and ask for your comments. We need to separate variable decelerations into active-stage (before second-stage) variables and second-stage variables. There is now much evidence that head compression is responsible for variable decelerations in the second stage of labor. One example is the almost universal occurrence of severe variables on traction with forceps. I firmly believe that the majority of severe variable decelerations and end-stage bradycardias seen in the second stage are caused by dural stimulation from head compression with subsequent vagal activity. You have evidence to the contrary in that you did relieve the end-stage bradycardia with amnioinfusion. I understand that Nageotte et al.[1] could not abolish second-stage variables with amnioinfusion.[1] Your results are at variance with theirs.

DR. STRONG (Closing). Dr. Goodlin, we have inferred relief of cord compression because we have been able to demonstrate by the amniotic fluid index an increase in the amniotic fluid volume. Miyazaki and Nevarez,[1] in their original article, suggested that the majority of the fluid reaccumulated in the lower uterine segment. You could interpret this to indicate cushioning to the fetal head. In our article we really did not address the question of where the fluid acccumulated. However, it is my feeling that it is the cord rather than the head that is protected by expansion of amniotic fluid volume.

Dr. Parer, the difference between my article and the

one by Nageotte et al. (and other articles reporting amnioinfusion) is that we determined the amniotic fluid volume on a regular, hourly basis. That determination is important to ensure that throughout labor amniotic fluid volume is retained in utero to provide cushioning, or whatever it is, during the course of labor. As the mother begins pushing, much of the amniotic fluid may be expelled. I reiterate that you not only expand the fluid volume, but that you need to maintain it during labor.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby-Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Ultrasonography-guided early amniocentesis in singleton pregnancies

Frederick W. Hanson, MD, Regina L. Happ, MD, Frances R. Tennant, PhD, Stacy Hune, MS, and Ann G. Peterson, RN, MN
Davis, California

Between October 1, 1986, and September 30, 1987, 1721 amniocenteses were performed at the University of California, Davis, Medical Center. Of these procedures 527 (30.6%) were early amniocenteses. Medical records were reviewed for maternal age, amniocentesis indication, color of amniotic fluid, gestational age, frequency of needle insertion, complications of amniocentesis and delivery, results of prenatal testing, and pregnancy outcome. Complete follow-up data were available for 517 (98.1%). There were 10 miscarriages before 28 weeks' gestation (1.9%), one loss after 28 weeks (0.2%), and one stillbirth (0.2%), resulting in a total postprocedural loss rate of 2.3%. Miscarriage within 2 weeks of amniocentesis occurred in four subjects (0.8%). (AM J OBSTET GYNECOL 1990;162:1376-83.)

Key words: Early amniocentesis, discolored amniotic fluid, miscarriage, stillbirth, amniotic fluid leakage

Prenatal diagnosis of chromosomal biochemical and neural tube defects has been widely accepted as a routine procedure in the management of obstetric patients. Amniocentesis has customarily been performed between 16 to 18 weeks' gestation. Patients and physicians, however, have increasingly requested earlier diagnosis for reassurance of the normality of the pregnancy or to allow earlier and safer interruption of pregnancy if indicated by detection of a fetal abnormality.

A spectrum of diagnostic procedures is now available to meet these demands and includes chorionic villus sampling (transcervical or transabdominal), earlier amniocentesis, and conventional amniocentesis.

In 1987 we published our initial report on earlier amniocentesis.[1] That report covered an extended time period with increasing operator experience and frequent modification of technique. Continuous ultrasonographic monitoring during amniocentesis was not used for the time period covered by that publication. It is the purpose of this report to reevaluate our experience performing earlier amniocentesis with the use of continuous ultrasonographic guidance.

Methods

The prenatal diagnosis program at the University of California, Davis, has been previously described.[2] More than 12,000 amniocentesis procedures have been performed since inception of the program in 1976. During the period covered by this study (October 1, 1986, through September 30, 1987) 1721 amniocentesis procedures were performed. The majority were performed by one of the authors (F. W. H.). Of these procedures 527 were accomplished before week 15 since the last menstrual period, and they are the subject of this report.

The data were evaluated for amniocentesis indication; gestational age at the time of amniocentesis (weeks since last menstrual period ± 1 week); color of amniotic fluid; pregnancy complications before amniocentesis, delivery complications, amniocentesis complications, and pregnancy outcome. For comparison with previously published studies pregnancy loss data were divided into the following categories: 2 weeks after amniocentesis, <28 weeks' gestation (miscarriage), ≥28 weeks' gestation (stillbirth), and neonatal death (within 1 week of birth). Loss data were further evaluated as to possible or probable relationships to amniocentesis.

The technique of amniocentesis used in our program was previously reported.[2] This has been modified to include continuous ultrasonographic monitoring to guide placement of the needle and monitor fetal movement during amniocentesis (Fig. 1). We use either an RT 3000 machine (General Electric, Milwaukee) or an ATL Ultramark 4 machine (Advanced Technology Laboratories, Inc., Bothell, Wash.) for this purpose.

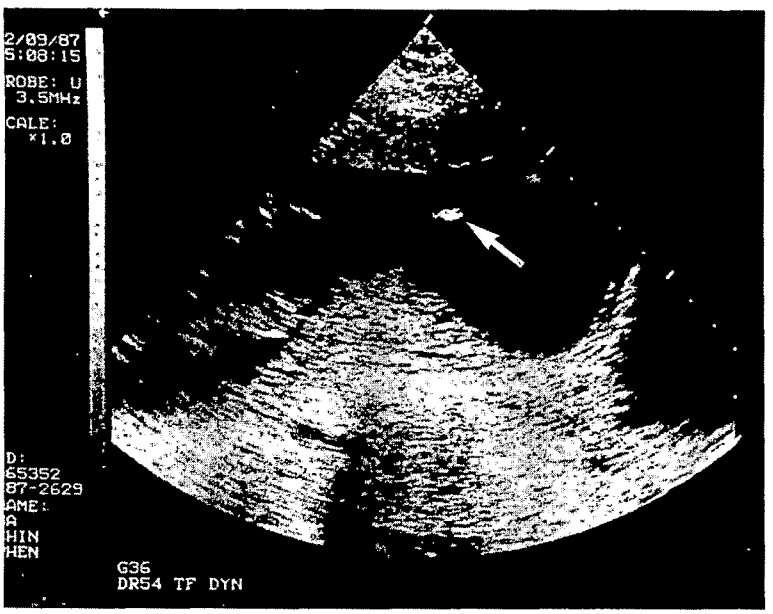

Fig. 1. Example of continuous ultrasonographic monitoring of needle placement in early amniocentesis. *Arrow* indicates tip of needle within amniotic fluid.

During the period covered by this study a 20 gauge spinal needle was used and a mean of 26 ml of amniotic fluid was removed. Currently we exclusively use a 22 gauge needle and remove approximately 1 ml of amniotic fluid for each week of gestational age.

Amniotic fluid was cultured with the in situ technique of Peakman.* Fifteen clones and five karyotypes were examined and analyzed. The experience of our cytogenetic laboratory in culture of amniotic fluid from 10- to 14-week pregnancies has recently been reported.[3] The mean time in culture is 8.8 days (SD, 1.5 days).

The program Microsoft Works and Statview 512+ (Abacus Concepts, Inc., Berkeley, Calif.) was used on a MacIntosh Plus microcomputer (Apple Computers, Cupertino, Calif.) to prepare summary tables.

Table I. Indications for amniocentesis

	No. of patients	%
Maternal age	462	87.7
Maternal anxiety	33	6.3
Family history/prior child with chromosome abnormality	20	3.8
Prior child with multiple congenital abnormalities	5	0.9
Family history/prior child with neural tube defect	5	0.9
Pregnancy at risk for metabolic disease	1	0.2
Fetal abnormality on ultrasonography	1	0.2

Results

The demographic data of the study population were not different from those published in our previous studies.[1, 2] The indications for amniocentesis are seen in Table I.

A total of 1721 amniocenteses were performed during the study period. There were 527 amniocenteses, representing 30.6% (527/1721) of the total, performed before 15 weeks since the last menstrual period. the patient distribution by gestational age is seen in Table II.

The frequency of needle insertion is shown in Table III. A total of 92% of the amniocenteses were successfully performed with a single needle insertion. One patient required retap because of failure of culture growth as a result of inadequate fluid volume obtained at amniocentesis.

The volume of amniotic fluid obtained at amniocentesis varied from 5 to 36 ml with a mean of 26.3 ml in those patients with a normal outcome. The mean fluid volume removed from those patients who had a fetal loss was 22.8 ml, varying between 12 to 36 ml.

Discolored amniotic fluid was obtained from 5.1% (27/527) of the amniocenteses. Only 8.3% (1/12) of the patients who had fetal loss had discolored fluid.

A total of 1.5% (8/527) patients required rescheduling. Seven were determined to be too early and one was because of culture failure.

Table IV shows the number of patients who had complications within 2 weeks of amniocentesis. A total of 503 (95.4%) did not have problems. Four patients (0.8%) had an unanticipated pregnancy loss within 2 weeks of amniocentesis. No data concerning potential complications were available for seven patients (1.3%).

Eight patients (1.5% of the total) had amniotic fluid leakage of several days' duration after amniocentesis. One of these patients, who had been bleeding and cramping before amniocentesis, miscarried a chromosomally normal fetus 3 weeks after amniocentesis. The pregnancy outcomes for the eight patients with amniotic fluid leakage are seen in Table V.

Table VI lists delivery complications. Vaginal delivery without complication was undergone by 72.4% of subjects (366/505). Cesarean section was the route of delivery for 22.8% (115/505). Fourteen patients (2.8%) had a number of complications such as premature labor, premature rupture of membranes, postpartum hemorrhage, retained placenta, and pregnancy-induced hypertension that were not considered of sufficient frequency to list separately.

Pregnancy outcome for all patients who underwent early amniocentesis is listed in Table VII. A total of 92.4% (474/513) of patients were delivered of a normal child.

Twelve patients (2.3%) were seen with a variety of outcomes such as macrosomia, hydrocephalus, cystic fibrosis, diaphragmatic hernia, congenital glaucoma, absent hand, hyperbilirubinemia, and dislocated knee and were placed in a category of outcome called "other." These were of insufficient frequency to rate

975	Vaginal delivery	Normal term
1497	Vaginal delivery	Born with dislocated knee at term

placement in individual categories. Four patients, representing 0.8% of the total (4/527), were seen with fetal death before amniocentesis.

Six patients (1.1%) had either structural or chromosomal abnormalities detected and chose to terminate their pregnancies. Ten patients (1.9%) were lost to follow-up.

Twelve patients, representing 2.3% of the total (12/523), had pregnancy losses at some point after the amniocentesis. Table VIII lists four cases or 0.8% (4/523) that appear to be amniocentesis-related although patient No. 161 was bleeding and cramping before amniocentesis. Table IX describes those losses that probably are not related to amniocentesis; eight cases are listed, representing 1.5% (8/523) of the total. If cases that are clearly not related to amniocentesis are eliminated such as Nos. 791 and 1146, the overall loss rate is 1.9% (10/523). The remaining six cases all had significant abnormal ultrasonographic findings or preamniocentesis pregnancy complications that could have been significant enough to explain the cause of the pregnancy loss. These factors included preamniocentesis bleeding with and without cramping, subamniotic hematoma, retroplacental fibroid or mass, and tight nuchal cord.

The overall loss rate of desired pregnancies in this study was 4.4% (23/517). This represents a combina-

tion of losses before amniocentesis (4), losses after amniocentesis (11), stillbirth (1), elective termination of a normal pregnancy (1), and elective termination of abnormal pregnancies (6). This figure includes only pregnancies with known outcomes.

Comment

Concerns with regard to the safety and hazards of prenatal diagnostic procedures have resulted in numerous reports with regard to midtrimester amniocentesis.[2, 4-8] Reported fetal loss rates have ranged from a low of 0.3%[8] to 2.89%.[4] A recently published report that evaluates the safety and efficacy of chorionic villus sampling showed a combined loss rate (spontaneous and missed abortion, termination of abnormal pregnancies, stillbirths, and neonatal deaths) for desired pregnancy of 7.2% in the chorionic villus sampling group and 5.7% in the amniocentesis group. After data adjustment it was concluded that the difference in loss rate for the two groups was 0.8%.[9]

It is difficult to establish an entirely comparable figure for our study population. Our overall loss rate of desired pregnancies was 4.4%.

In evaluation of procedural risk it is important to realize and consider that performance of these prenatal diagnostic procedures is superimposed on a certain background spontaneous abortion rate. The earlier a procedure is performed, the higher is this rate and the longer is the opportunity for the patient to have a spontaneous abortion. In our previous publications we did not consider background loss data in reporting our results.[1, 2]

It has long been considered that 15% to 20% of recognized pregnancies result in spontaneous abortion before 20 weeks' gestation. Liu et al.[10] followed up 1068 pregnancies that were confirmed to be normal by ultrasonography (before 14 weeks' gestation) until 28 weeks' gestation. They reported an overall 2.7% spontaneous abortion rate with 1.5% occurring before week 16 and 1.2% between 16 to 28 weeks' gestation. They also suggested a slightly higher spontaneous abortion rate (1.8% versus 1.3%) between 11 to 16 weeks' gestation for primigravid patients, as compared with multigravid patients. Threatened miscarriage was associated with a 38% fetal loss rate. This may have been a factor in 42% (5/12) of our losses.

Gilmore and McNay[11] followed up 2144 pregnancies that were established as normal by ultrasonography before 10 weeks' gestation. An overall 2.1% spontaneous abortion rate occurred. This rate tended to increase with increasing maternal age, being 2.6% between ages 35 to 39 years and 13.6% at age ≥40 years. Wilson et al.[11] published a similar study and showed comparable results with an overall spontaneous abortion rate of 2.13% (up to 20 weeks' gestation) and an increasing risk with advancing maternal age. Furthermore it should be noted that the 1976 National Institute of Child Health and Human Development study of amniocentesis published a 3.2% spontaneous abortion rate* for their control group of race, gravidity, and family income–matched women.[4] However, these pregnancies were not shown to be normal by ultrasonography before amniocentesis.

Compared with our previously published total postprocedural loss rate of 4.7%,[1] the figure of 2.3% for this study suggests significant improvement. The addition of continuous ultrasonographic guidance has contributed significantly to this improvement. Increased experience has also contributed. Technically,

early amniocentesis becomes easy to perform once one gains experience and with that experience confidence. We have learned that certain clinical situations such as patients with extreme obesity, a retroverted uterus with intervening bladder and bowel, or amnion chorion separation with an undulating amnion are best rescheduled although early amniocentesis is technically feasible. Since completion of this study protocol we have further modified our procedure to include exclusive use of a 22 gauge needle and removal of 1 ml of fluid for each gestational week. We have confidence in our laboratory to culture early amniotic fluid.[3] α-Fetoprotein levels can also be assayed and confidently interpreted on these fluids.[12]

In summary, continuous ultrasonographic guidance appears to decrease the risks of early amniocentesis and add to the technical ease of obtaining the amniotic fluid specimens. When combined with in situ cell culture and reliable α-fetoprotein assay it offers patients a viable option for early prenatal diagnosis.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. Lewis Shenker, Tucson, Arizona. Hanson et al.[1] presented their first article on this topic at the 1986 meeting of this society. They described 542 procedures performed before 15 weeks' gestation. Only four (0.7%) were done at 11 weeks' gestation; 36 (6.7%) at 12 weeks; and 149 (27.5%) at 13 weeks. The majority

of the described procedures (352 or 65.1%) were done at 14 weeks' gestation. In his discussion, Dr. Goodlin did not think that it was unusual to perform amniocentesis as early as 14 weeks. This observation has even more validity today.

The present article describes the addition of ultrasonographic guidance to the performance of early amniocentesis. Dr. Hanson now does early amniocentesis in 30.6% of his patients, compared with the previous study when early amniocentesis comprised 11.4%. A total of 57 of the 527 procedures were performed in the group at 10 to 12 weeks' gestation. The conventional definition of early amniocentesis is applied to procedures at ≤14 weeks' gestation and possibly justifies the inclusion of 13- and 14-week gestations in both of Dr. Hanson's series. I am very critical of this definition of early amniocentesis and would like to see it modified to include only those procedures performed from 9 through 12 weeks' gestation. Until there is more reported experience at these gestational ages, a true comparison of this procedure with chorionic villus sampling with respect to results and complications will be impossible.

There is decreased pregnancy loss in the recent series compared with the original. Dr. Hanson chooses to credit this to the use of ultrasonographic guidance and increased experience. My prejudice is to give more weight to the latter. Especially with very early amniocentesis, the choice of needle sites is limited; either a favorable site exists or it does not. If a direct perpendicular track to the amniotic sac is not present, my preference is to reschedule the procedure. Measurement of depth from the skin surface will make aspiration of amniotic fluid relatively easy. I have not felt the need for ultrasonographic monitoring during the procedure, but will spend extra time scanning and planning the approach before the needle insertion.

I would like to ask Dr. Hanson two questions. Does he feel confident about the normal range of values for amniotic fluid α-fetoprotein and acetylcholinesterase values at gestational ages of 10 through 14 weeks? How does he manage twins diagnosed by ultrasonography at the time of scheduled genetic amniocentesis at 10 weeks' gestation?

I congratulate Dr. Hanson on his article with regard to this interesting series of early amniocenteses. It will help us to counsel patients in their choice of early versus conventional amniocentesis. I look forward to seeing reports on future series of patients in the early group of 10 to 12 weeks' gestation.

DR. ROBERT GOODLIN, Denver, Colorado. I remember that you were always a very strong advocate of size 18 needles and am curious why you are suddenly going to size 22. I was intrigued by your interesting sex ratio—many more females than males. Who does your ultrasonic guidance? I know that when I do amniocentesis, if the technician is highly skilled, there is no problem. However, if he or she is less skilled, I obtain fluid less often. My final question is what do you do when your technician finds bradycardia?

DR. RICHARD ALLEN, Portland, Oregon. I discussed this topic with two people who do most of these procedures in Portland. Both prefer chorionic villus sampling in early pregnancy because they believe that when they try amniocentesis earlier than the conventional time they get a higher failure rate. They both stated independently that if they were doing a DNA profile they could get enough fluid, but if they were doing a full chromosome panel they might not be able to get enough fluid for cell cultures to grow. I am curious as to whether you have had any problem with cell cultures growing in these earlier amniocenteses.

DR. HANSON (Closing). I certainly agree with Dr. Shenker's suggested modification of the definition of early amniocentesis. We are now doing 50% of our amniocentesis at <15 weeks' gestation, and 50% of those are at 12 weeks' gestation. Our experience is unchanged. We recently published an article[1] that was a follow-up to our original article[2] on early amniotic fluid α-fetoprotein levels. We are very confident of the values. The SD was very tight. The reliability of acetylcholinesterase is a little different. Dr. Crandall believes that at least down to 12 weeks' gestation it is very, very reliable; below 12 weeks, with experience it is still interpretable. She will present a paper[3] in the fall on this subject. Although I have done a fair number of twins early, I reschedule because I am going to be tapping two sacs and taking a larger total volume of fluid. I have no scientific reason for doing this.

Dr. Goodlin, I have not used an 18 gauge needle in years. There have been articles that suggested 18 gauge needles are associated with increased fetal morbidity so I switched to 20 gauge and now I use 22 gauge exclusively for early amniocentesis. If the needle is to be inserted near the umbilicus or higher I will use a 20 gauge. I can withdraw fluid faster with a 20 gauge than I can with a 22 gauge, and I like to get in and out quickly. I cannot explain the difference in the fetal sex ratio. The ultrasonographers that I work with are superb and I rely on them to help me identify the needle tip because I have my hands full manipulating the needle and watching the ultrasonographic screen. I listen to them to make the needed adjustments. I do find that continuous monitoring is valuable because I can redirect the needle away from the fetus, making midcourse adjustments. The need for a retap is almost nonexistent with the use of continuous guidance. Continuous ultrasonographic guidance is especially important with early amniocentesis. You need to be able to get adjacent to the amniotic membrane and then perform a sharp popping motion (through the amnion), rather than a steady motion, to avoid pushing the amniotic membranes to the posterior well of the uterus.

Dr. Allen, we have not had trouble with cell cultures. As you can see, the only failure we have had in this series was a situation in which I failed to obtain sufficient fluid. One of our fears when we first started doing early amniocentesis was culture failure because early amniotic fluid contains fewer viable cells. However, they seem to make up for their decreased numbers by growing more vigorously in tissue culture. In almost all cases we are able to get at least 15 clones and 5 karyotypes, which are the numbers the state recommends as the standard.

Seventy-one quadruplet pregnancies: Management and outcome

Michael S. Collins, MD,[a] and Janet A. Bleyl, BA[b]
Portland, Oregon, and Stockton, California

This article reviews the epidemiology, management, and outcome of 71 quadruplet pregnancies that occurred between 1980 and 1989. A study of detailed medical questionnaires and medical records revealed that 67 (94%) of the pregnancies followed ovulation induction therapy. A majority of the pregnancies were diagnosed by 9.3 weeks' gestation and bed rest was institutec by 16.7 weeks; 14% of women had cervical cerclages. Tocolytic agents were used in 59 (83%) of the group beginning at 24.5 weeks' gestation. The mean gestational age at delivery was 31.4 weeks and the mean birth weight was 1482 gm. Cesarean sections were performed in 89% of the cases. The average maternal weight gain was 45.8 pounds. Of the 284 fetuses, there were six first-trimester losses (including one ectopic pregnancy), 10 stillbirths and 33 neonatal deaths, resulting in a stillbrith rate of 29 per 1000, and corrected neonatal and perinatal mortality rates of 37 per 1000 and 67 per 1000, respectively. Other than premature labor, the most common maternal complications were first-trimester bleeding (35%), toxem a (32%), and anemia (25%). The quadruplet fetal growth curve parallels the singleton 25th percentile until 34 weeks, when it drops below the 10th percentile. These data suggest that a majority of quadruplets are delivered after 28 weeks and a viable outcome is expected. Because of retarded growth after 34 weeks, delivery should be considered at 34 weeks in most cases. (Am J Obstet Gynecol 1990;162:1384-92.)

Key words: Quadruplets, growth curve, complications, prematurity

Since the introduction of gonadotropin therapy in 1959 and clomiphene citrate (Clomid) in 1961 for ovulation induction, a major increase in multifetal pregnancies has occurred.[1-6] Hellin's rule for approximating multiple births is no longer applicable. Twins, triplets, and quadruplets exceed the 1 in 90, 1 in 90^2, and 1 in 90^3 predictions based on this hypothesis.[2] Multiple gestations occur in 6% to 8% of pregnancies induced by Clomid and 20% to 40% of those associated with gonadotropins, but most of these are twins. Quadruplets are reported in 0.3% of Clomid-induced pregnancies and 2.6% of gonadotropin-induced gestations.[1] The actual incidence of quadruplet gestations since the advent of modern reproductive technology is unknown. Quoted incidences range from 1 in 677,000[3] to 1 in 5370.[4] More importantly, information on perinatal outcomes for larger order gestations is scanty; thus counseling pregnant patients with supermultiples and planning their management is hampered.

A study of 71 quadruplet pregnancies was undertaken to survey pregnancy management and outcomes. The largest modern series of quadruplets reported six pregnancies.[4, 5] A recent review found 17 pregnancies discussed in a total of six papers.[6] Although still rare, quadruplets occur frequently enough that a review of a series this size is warranted to describe their natural history in the 1980s.

Material and methods

Detailed medical questionnaires were collected through The Triplet Connection, a support group for mothers of supermultiples. These surveys were designed by a physician advisory panel to accumulate data on triplet or greater pregnancies. The Triplet Connection is a nonprofit organization that collects and disseminates information on superfetal gestations. It works closely with an advisory panel, which includes perinatologists and obstetrician-gynecologists.

One hundred forty-two women with delivered and undelivered quadruplet pregnancies have contacted The Triplet Connection for information. Seventy-one of the 121 delivered pregnancies supplied adequate information through completed medical questionnaires, medical records, and hospital summaries and are the subject of this report. Fifty pregnancies were excluded because there was no questionnaire available. There were 17 fetal and neonatal losses in this group of excluded pregnancies. Sixty-three precent of the women established contact with the organization during pregnancy and were followed up on a prospective

basis. The following information was requested: patient age, gravity, parity, prenatal weight, total weight gain, timing of diagnosis, use of ovulation induction agents, and fertility procedures. Questions on prenatal management included the timing and length of bed rest; the use of tocolysis, steroids, cerclage, and home monitoring; the number and length of hospitalizations, and the prenatal complications. Information on timing and method of delivery, birth weight, neonatal course, and postpartum complications was obtained. A growth curve was derived from the birth weights from pregnancies without fetal losses. This curve was compared with a singleton growth curve.[7]

Results

A profile of the 69 patients who were delivered of 71 quadruplet pregnancies is reported in Table I. Mean maternal age was 29.3 years (range, 19 to 36 years); 41 patients were nulliparous. Multiple births had previously occurred in five of these women. There were two patients with twins and one with triplets. Two surveyed mothers reported two quadruplet pregnancies, all of which are included. The group had above-average education and income levels; 75% had college or postgraduate degrees; 76% had family incomes of >$30,000.

The 71 pregnancies were delivered in 27 states and two Canadian provinces. A higher number of respondents were from California (n = 9). Illinois (n = 6), Massachusetts (n = 5), Michigan (n = 5), and Indiana (n = 5). Most of the pregnancies were managed by perinatologists (69%) in level III units (86%). General obstetrician-gynecologists provided care for 30% of these pregnancies with perinatal consultation. Only 13% of the women were delivered in a level II facility.

Ovulation-inducing agents were used in 67 of 71 pregnancies (94%); only four quadruplet gestations were conceived spontaneously. Clomiphene as a single agent was associated with 15 pregnancies. Over half (n = 8) of these 15 occurred with the first course at a starting dose of 50 mg per day for 5 days.

A variety of gonadotropin regimens with combinations of Pergonal, menotropin, human chorionic gonadotropin, and Clomid caused 52 (73%) of the quadruplets; gamete intrafallopian transfer resulted in 18% (n = 13), and in vitro fertilization 7% (n = 5) of the multiples. The gonadotropin regimens alone, without egg retrieval techniques, accounted for 34 of the 52 gonadotropin-induced pregnancies.

In two of the four spontaneously conceived quadruplet pregnancies, identical siblings occurred. The only set of identical quadruplets were female and were delivered at 28 weeks. One of the four siblings died at 14 days of multiple anomalies. A biovular pregnancy, with three identical boys and one girl, was delivered at 34 weeks and all infants survived. The third spontaneously conceived quadruplet pregnancy was delivered of four fraternal girls. The fourth patient was hypothyroid and was delivered of three nonidentical girls and one boy at 26½ weeks. One neonatal death resulted from sepsis and respiratory distress syndrome.

Table I. Profile of 69 patients with 71 quadruplet pregnancies

Mean maternal age (yr)		29.3
Nulliparous (n = 41)		59%
Prior multiple pregnancies		5
College or postgraduate education		75%
Income >$30,000		76%
Ovulation induction		
Spontaneous	4	(6%)
Clomid (alone)	15	(21%)
Gonadotropin regimens	52	(73%)
Gamete intrafallopian transfer	13	(18%)
In vitro fertilization	5	(7%)

Chronologically, over half (n = 37) of the study group was delivered in 1988 or during the first 6 months of 1989 (Fig. 1). All gamete intrafallopian transfer and in vitro fertilization pregnancies were in this period. The broader application of ovulation-inducing agents and increased reporting to The Triplet Connection are logical explanations for this trend.

Important trends in management are noted from study of the accumulated data (Table II). Ultrasonography has played a valuable role in diagnosis and monitoring of growth and viability in these pregnancies. In all patients the diagnosis of supermultiples was made before delivery, although two pregnancies were misdiagnosed as triplets until delivery. The average timing of ultrasonographic diagnosis was 9.3 weeks (range, 4 to 32 weeks). Growth was closely monitored with an average of 11.2 ultrasonographic exams per pregnancy; a total of 790 exams were done in 70 pregnancies. Early bed rest is evidenced by the mean onset of partial or total bed rest at 16.7 weeks, with an average duration of 13.1 weeks (range, 4 to 24 weeks).

The mean maternal weight gain in 70 pregnancies was 45.8 pounds (range, 11 to 100 pounds). Patients answering questions on diet consumed between 1800 and 6000 calories per day with high protein levels. Dietary intake was a major problem in the first trimester with hyperemesis and after 26 weeks when extreme abdominal distention was notable. No significant correlation existed between maternal weight gain and newborn birth weight.

Ten patients underwent cerclage for premature cervical changes. Sutures were placed at 16.6 weeks' gestation for an average duration of 14.6 weeks. These patients were delivered at a mean gestational age of 31.2 weeks, which was not different from the noncerclage group.

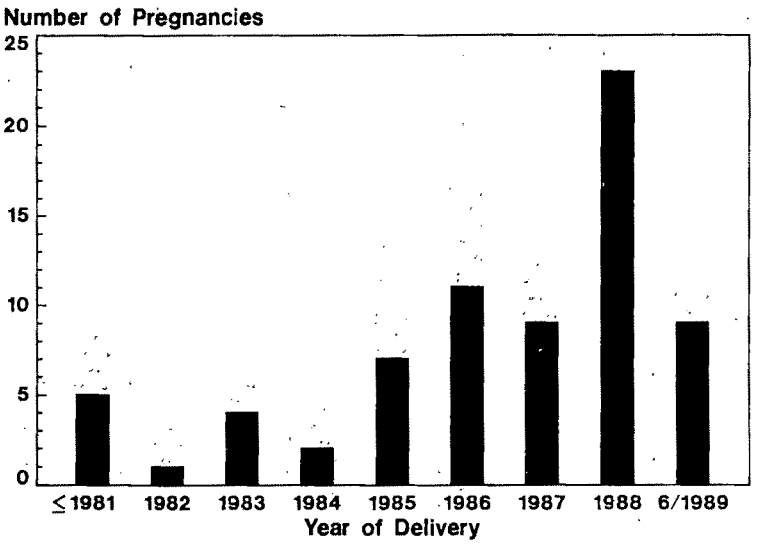

Fig. 1. Chronologic distribution of 71 quadruplet pregnancy deliveries.

Patients reported that home fetal monitoring (TOKOS) was helpful in differentiating contractions from excessive fetal movement. Home monitoring began in 1986. Twenty of 52 patients (38%) who were delivered since its availability have used this system either at home or in the hospital at bed rest.

Steroid therapy to enhance fetal lung maturity was used in 18% of pregnancies for periods of 1 to 8 weeks. In all cases, it was used on an inpatient basis when delivery appeared imminent. It had no obvious impact on mortality rates.

Tocolysis was used in 83% (n = 59) of pregnancies with the mean onset of premature labor at 24.5 weeks. It was difficult to differentiate between prophylactic and therapeutic use of tocolysis. Terbutaline, ritodrine, and magnesium sulfate were used singly or in combination. One half of the women were treated with terbutaline. Three patients were managed with the terbutaline mini-pump. Indomethacin and progesterone were used as supplemental therapy.

Hospital admission data were difficult to interpret. As expected, lengthy stays and frequent admissions were common. The most common complications necessitating admission were premature labor, toxemia, and bleeding.

The proper method of delivery for supermultiples is debated in the literature.[4,6] The trend in recent years has been to proceed with operative delivery; 89% of the pregnancies were delivered by cesarean section, 8% by vaginal delivery, and 3% by a combined vaginal and cesarean delivery.

Major prenatal complications included premature labor, first-trimester bleeding, incompetent cervix, pregnancy-induced hypertension, and anemia (Table III). Premature labor complicated 70 of 71 pregnancies. Its mean onset was 24.5 weeks (range, 20 weeks to term). The only pregnancy without premature contractions was delivered of three stillborn infants and one live infant at 38 weeks. Two other pregnancies were delivered after 37 weeks. One patient had been hospitalized for 24 weeks. The other had previously been delivered of triplets, had a cerclage, and remained at bed rest for 18 weeks. She was delivered by a third cesarean section at 38 weeks when the membranes ruptured.

First-trimester bleeding was reported in 25 pregnancies (35%). Four of five prenancies with a "vanishing fetus" (in which four living fetuses reduced to three) had early bleeding. Perinatal mortality, incidence of premature labor, and timing of delivery did not differ significantly for women with first-trimester bleeding. However, six of these patients experienced postpartum hemorrhage and four required transfusion.

It was determined from the questionnaire data that pregnancy-induced hypertension developed in 23 patients. Mean maternal age, delivery date, and bed rest for these women were not statistically different from the normotensive patients. Six of the 23 patients received steroids to enhance pulmonary maturity. All were admitted when pregnancy-induced hypertension was diagnosed. Seven neonatal deaths occurred in pregnancies complicated by preeclampsia and five of these seven were delivered at less than 29 weeks' gestation. Two mothers had pulmonary edema and congestive heart failure. Both had preexisting anemia and suffered postpartum hemorrhages. One had received betamethasone for 6 weeks before delivery.

In addition to the 10 cerclages mentioned earlier, surgical procedures included two salpingo-oophorectomies, one salpingectomy, and a pituitary tu-

mor removal. The 10 cerclages were done at 16.6 weeks (range, 12 to 25 weeks) and helped maintain pregnancies until a mean delivery of 31.2 weeks (range, 28 to 38 weeks). Eight of 10 cerclage patients received tocolysis. Both salpingo-oophorectomies were done for ovarian hyperstimulation, which was complicated by a ruptured hemorrhagic cyst in one case and ovarian torsion in the other. The procedures were done at 18 and 20 weeks, respectively. A salpingectomy at 11 weeks' gestation was needed for a ruptured ectopic pregnancy. This patient subsequently had a cerclage placed at 20 weeks and was then delivered at 29 weeks. All neonates survived with minimal respiratory distress.

A patient whose first set of quadruplets died at 22 weeks underwent transsphenoidal removal of an enlarging prolactinoma. Surgery was performed at 20 weeks when medical therapy failed and visual loss progressed. Four healthy girls were delivered by cesarean section at 36 weeks.

Postpartum hemorrhage was reported in 21% ($n = 15$) of the surveyed mothers and 13% ($n = 9$) required transfusion. Excessive blood loss in two patients necessitated six 1-unit transfusions. Hemorrhages were caused by abruptio placentae in two cases and uterine atony in seven. One case of abruptio placentae at 20 weeks resulted in four neonatal deaths and the patient required curettage plus transfusion for retained products of conception. The other case occurred at 33 weeks, but all four infants survived. In addition to requiring transfusion, this mother had thrombophlebitis and received anticoagulant therapy for 4 months post partum. One patient with persistent postpartum bleeding caused by subinvolution of the uterus had curettage 3 weeks after delivery. The 15 pregnancies complicated by postpartum hemorrhage were delivered at a mean gestational age of 32.5 weeks and therefore had a total uterine volume that was comparable with the group that did not report excessive bleeding.

Outcome for these 71 pregnancies is outlined in Table IV. Although premature labor became evident at 24.5 weeks' gestation, delivery occurred an average of 7 weeks later, at 31.4 weeks ± 3.6 (mean ± SD). Delivery time ranged from 20 to 38 weeks' gestation. Fig. 2 demonstrates that most deliveries (67%) occurred after the 31.4 week mean, with clustering between 31 and 35 weeks. In fact, 73% of pregnancies were delivered after 30 weeks and 87% were delivered after 28 weeks.

Birth weight ranged from 255 to 2914 gm. The group mean was 1482 gm. This calculation excluded all first-trimester losses and stillbirths. A gender ratio of 1.3 to 1.0 existed, with 158 females and 118 males identified and reported. Sex was unknown in eight fetuses.

Graphing all birth weights at each gestational age allows some helpful observations (Fig. 3). Live births,

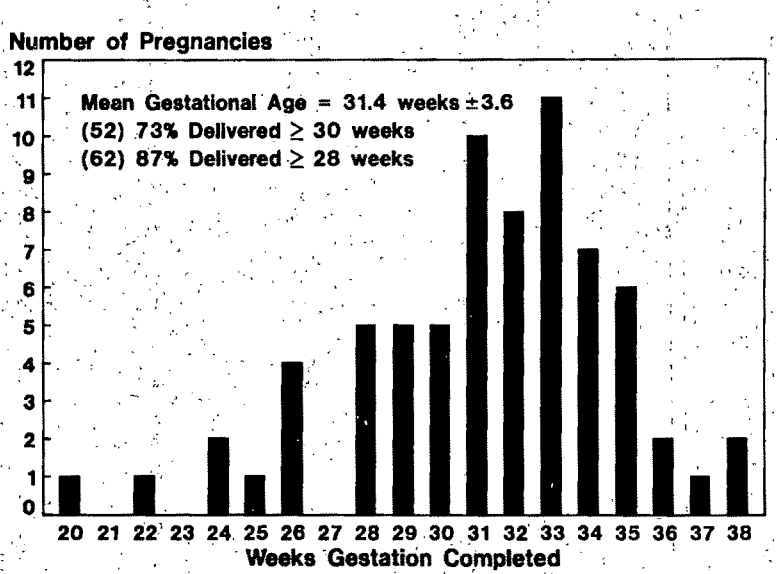

Fig. 2. Distribution of 71 quadruplet pregnancies by gestational age at delivery.

Table IV. Pregnancy outcome

Premature labor	Onset 24.5 wk (range, 20 to 37 wk)	
Gestational age at delivery	31.4 ± 3.6 wk (mean ± SD) (Range, 20-38 wk) 87% (n = 62) delivered >28 wk	
Mean birth weight	1482 gm (Range, 255 to 2919 gm)	
Fetal sex		
Male 118		
Female 158		
Unknown 8		
Pregnancy losses		
Missed abortions		5

Neonatal deaths		33
20-27 wk	24	
28-31 wk	8	
≥32 wk	1	
Sudden infant death syndrome (2½ mo, 4½ mo)		2

stillbirths, neonatal deaths, and missed abortions or vanishing fetuses are depicted by the symbols on the graph legend. Median birth weights were calculated after excluding pregnancies in which a stillbirth or missed abortion occurred. Therefore only pregnancies resulting in delivery of four living neonates were used in mean and median birth weight determination.

Of note were the concentration of neonatal deaths less than 28 weeks and the stillbirth occurrence after 32 weeks. "Vanishing fetuses," as mentioned earlier, were first-trimester missed abortions that had early ultrasonographically documented heart tones. The stillbirths along the baseline occurred months before delivery of the pregnancy and had no weight reported.

Fetal growth progressed in a linear fashion until 32 weeks when it slowed. By superimposing percentiles derived from singleton delivery data[7] and plotting the medians for quadruplets, this growth deceleration becomes more obvious (Fig. 4).

Less than 20% of quadruplet fetuses exceed the 50th percentile for singletons. Only six fetuses exceed the 75th percentile and most of these were delivered before 32 weeks. The "growth-retarded" fetuses (<10th percentile) dramatically increased at 34 weeks. Less than one fourth of the fetuses are below the 10th percentile before 34 weeks, whereas 62% are below that level after 34 weeks; χ^2 square analysis shows this difference is significant ($p < 0.001$).

Comparison of the quadruplet median birth weight curve with the singleton percentiles better illustrates this difference (Fig. 5). Growth approximates the 25th percentile for singletons until 34 weeks, when the quadruplet median birth weight drops below the 10th percentile for singletons. From 34 weeks until birth, the majority of quadruplet fetuses are "growth retarded" by singleton standards.

Fetal mortality consisted of one ectopic pregnancy, five vanishing fetuses or missed abortions, and 10 stillbirths. The six pregnancies with first-trimester losses all progressed normally to delivery between 31 and 35 weeks. In the missed abortions, four living fetuses spontaneously reduced to three with loss of heart activity in one fetus early in the pregnancy.

Table V details the 10 stillborn infants. Six died months before delivery and had no notable effect on the live-born siblings. Four fetuses died between 32 and

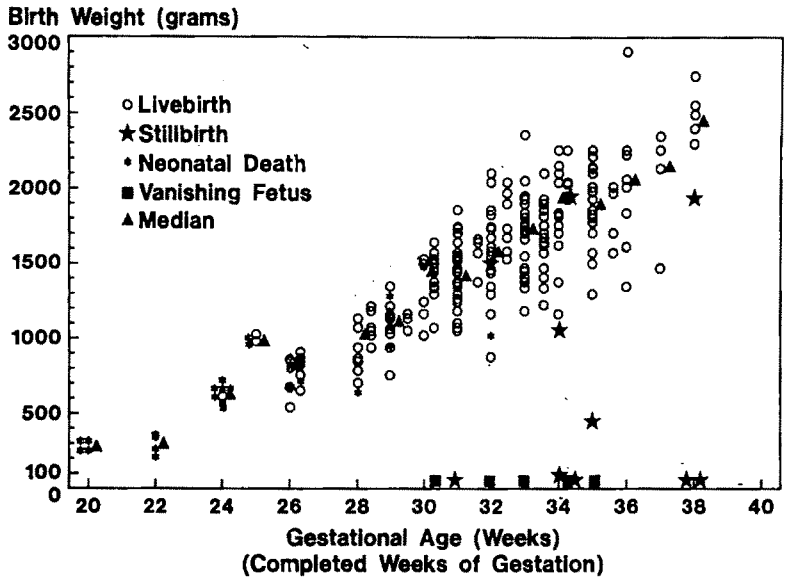

Fig. 3. Birth weights of 284 quadruplets arranged by gestational age and coded as live births (n = 235), neonatal deaths (n = 33), stillbirths (n = 10), or vanishing fetuses (n = 5). Median birth weights were calculated excluding pregnancies with any pregnancy loss.

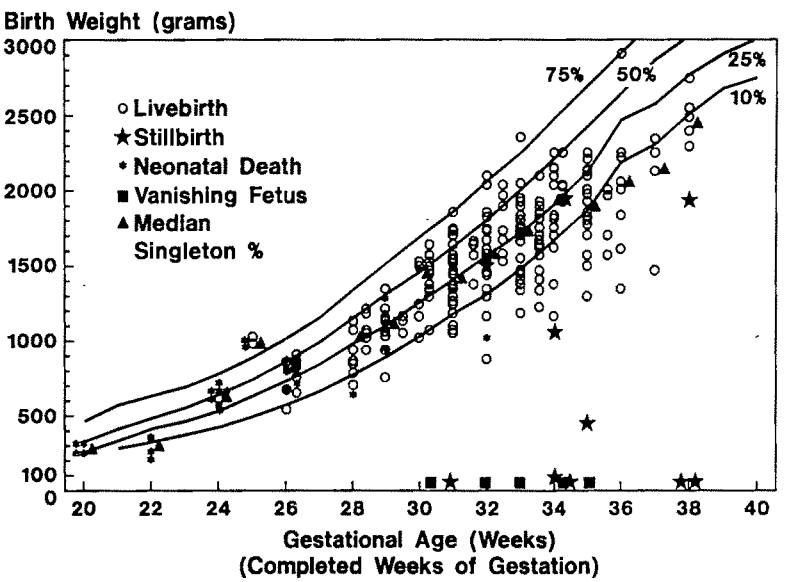

Fig. 4. Comparison of quadruplet birth weights with singleton percentiles for fetal weight.

38 weeks' gestation, within days of the delivery data. Of note were three intrauterine fetal deaths that occurred in a single pregnancy delivered at 38 weeks. Identical twins expired at 18 weeks and later, just before delivery, a fraternal sibling (1924 gm) died. Another pregnancy complicated by multiple stillbirths was delivered at 34 weeks. An unexplained fraternal 22-week loss preceded the 33½-week death of a markedly discordant identical twin. At birth the live twin weighed 1018 gm more than its stillborn counterpart. A mother with 12 weeks of bleeding, a history of smoking, and a previous pregnancy with intrauterine growth retardation had a stillbirth at 20 weeks. The remaining four fetal deaths are detailed in the table. Excluding the twin intrauterine fetal demises at 18 weeks as abortions, eight true stillbirths in 278 quadruplet fetuses yields a stillbirth rate of 29 per 1000.

Thirty-three neonatal deaths occurred in the 268 live births. Twenty-four infants who died during the neonatal period were delivered before 28 weeks' gestation and weighed under 1 kg. Eight were delivered between 28 and 30 weeks, with birth weights between 900 and

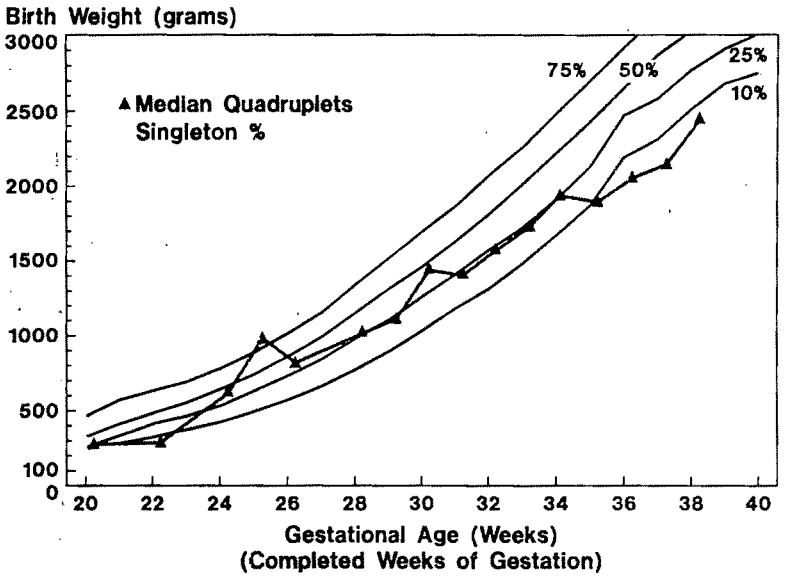

Fig. 5. Median quadruplet birth weights compared with percentiles for singleton birth weights.

Table V. Stillbirths

Delivery (wk)	*n*	*Details of death*
38	3	1 Pregnancy; identical twins died 18 wk, fraternal sibling died at 38 wk, 1924 gm
35	1	Intrauterine fetal death 20 wk, smoker, previous intrauterine growth retardation
34	2	1 Pregnancy; 22 wk intrauterine fetal death, 33 wk discordant identical twin (1047 vs 2065 gm)
34	1	Potter's syndrome
34	1	Cord accident, birth weight 1953 gm
32	1	Oligohydramnios
31	1	Neural tube defect—hydrocephalus

Table VI. Perinatal mortality

Stillbirth rate	29/1000
Neonatal mortality rate	123/1000
Corrected for <28 wk	37/1000
Perinatal mortality rate	147/1000
Corrected	67/1000

1400 gm. The latest neonatal death occurred at 32 weeks and the infant weighed 1000 gm at birth. The infant was significantly growth-retarded and died after a repair of a patent ductus arteriosus.

The neonatal mortality rate is 33 per 268 (123/1000). If newborn infants <28 weeks are excluded, the corrected neonatal mortality rate is 9 per 244 (37/1000). Three infants who died in the neonatal period weighed less than 1000 gm at birth but are included.

A perinatal mortality rate of 147 per 1000 (Table VI) is calculated if all losses before 20 weeks are included. The majority of losses are a result of severe prematurity (<28 weeks). By correcting for neonatal deaths that occurred before 28 weeks, a corrected perinatal mortality rate is 67 per 1000.

Sudden infant death syndrome occurred in two infants. The first was a growth-retarded boy delivered at 34 weeks. He weighed 1160 gm, 700 gm less than his nearest-sized sibling. Death occurred at 10 weeks of infancy, 6 weeks after hospital discharge. The second infant was a girl born at 31 weeks. She weighed 20 gm more than the mean sibling birth weight, was discharged 6 weeks after delivery, and died at 4½ months of age.

Comment

McKeown and Record[8] published outcome data of 27 quadruplet pregnancies that occurred between 1931 and 1951 in Britain. This had been the largest series to date. The average gestational age cited was 33.8 weeks and the mean fetal birth weight was 1394 gm. These figures are surprisingly close to the 31.4 weeks and 1482 gm we report for our series of 71 quadruplet pregnancies. The British series had a corrected perinatal mortality of 509 per 1000. This was significantly different from the 67 per 1000 reported here.

Criticism of methodology in our study is warranted. Two major limitations of the questionnaire format are (1) bad outcomes can select out, and (2) self reporting subjects data to reporting inaccuracy. Over 63% of patients have contacted The Triplet connection during their pregnancies; thus telephone follow-up is possible when questionnaires are not returned. The 50 delivered pregnancies excluded for lack of a questionnaire were known to have 17 losses in 200 fetuses or an un-

corrected perinatal mortality of 8.5 per 1000, which is better than the figure reported for the 71 studied pregnancies. Their inclusion would only lower the perinatal mortality.

The sample selection is biased because the study women had to contact The Triplet Connection and complete the detailed questionnaire to be included. They are motivated, well educated, and had better than average demographic characteristics. Over 90% of quadruplets result from state-of-the-art reproductive technology, which is sometimes only a possibility for these types of individuals. Hence preselection has occurred long before quadruplet conception does. The demographics of the group, it seems, would also enhance the accuracy and reliability of the self reporting.

Modern quadruplets are an iatrogenic phenomenon. Polyovulation was induced in 94% of this group. The margin between a hyperstimulatory dose and minimum effective dose of ovulatory stimulants is narrow; this has been described for gonadotropins[1] but not for clomiphene. It was surprising to find that eight of the 15 Clomid quadruplet conceptions occurred with the first treatment cycle and with a starting dose of 50 mg. The number of gamete intrafallopian transfer ($n = 13$) and in vitro fertilization ($n = 5$) quadruplet gestations in this group could, however, be reduced. With improved technology and cryopreservation, a more appropriate number of eggs or preembryos could be used.

If there is a natural history for the quadruplet pregnancy, one would profile the typical patient as being 29.3 years of age, nulliparous, well educated, with a better than average income, who used an ovulatory stimulant to conceive. Diagnosis of multiple pregnancy was generally made at 9 to 10 weeks and the pregnancy was followed very closely with serial ultrasonography. Bed rest began at 16 weeks. Premature labor occurred by 24 weeks and tocolysis was used. A weight gain of 46 pounds and a period of bed rest lasting 13 weeks could be anticipated. Delivery would be by cesarean section at 31 weeks in a level III hospital, with the patient cared for by a perinatologist. The mean quadruplet birth weight is 1482 gm. The risk for stillbirth begins around 32 weeks. The risk of neonatal death ends at about 28 weeks. There is a 93% chance of survival after the pregnancy reaches 28 weeks; over 85% of these pregnancies reached that mark.

In conclusion, a natural history of this multifetal gestation can be described with the data from 71 quadruplet pregnancies. The outcome was better than expected: 87% of pregnancies were delivered after 28 weeks. Corrected neonatal and perinatal mortality rates were 37 per 1000 and 67 per 1000. After 34 weeks, quadruplet fetal growth was retarded, intrauterine deaths increased, and no neonatal deaths occurred. Once that milestone is reached, delivery is a reasonable consideration should risks involved warrant it.

Discussion

DR. JAMES J. M. MORAN, Santa Monica, California. I would like to compliment the authors on their excellent article on the modern management and outcome of quadruplet pregnancies in the United States. It was obviously the result of extensive and tedious field research.

Despite the inherent problems mentioned in this type of research, several problems in the successful management of these cases were noteworthy: a high incidence of premature labor, pregnancy-induced hypertension, and bleeding. It appears from their data that early bed rest, use of tocolytic agents, and frequent use of ultrasonographic examinations appear to be beneficial in the successful outcome of these cases. Of current interest is the use of home monitoring and home nonstress testing, which may be helpful and cost effective in the prevention of preterm delivery and avoidable stillbirth.

It would appear that the use of antenatal steroids, especially for extended periods of time, which has become more popular, may prove to be somewhat risky and must be carefully monitored.

The thorny ethical problem of selective termination of one or more fetuses in grand-multiple pregnancies entails problems never before encountered. Should we terminate some fetuses to save others, especially if the parents plan to abort the entire pregnancy to avoid the known hazards? How do we choose those to live and those to die? Evans et al.[1] discuss these ethical issues in a very thorough article. They had four cases of grand-multiple pregnancies managed by selective termination of all but two fetuses in each patient. Two pregnancies were successful in outcome, but the other two failed to bring any live fetuses to term. In fact, in one case one of the remaining twins had renal agenesis. Thus better and earlier diagnostic techniques are needed before one embarks on such a controversial course.

Since this is generally an iatrogenic disease,with only

6% being spontaneous occurrences, it would appear that prevention of this phenomenon would help to prevent the difficulties of premature labor, the necessity for prolonged bed rest, and the frightening ethical decisions mentioned above.

Finally, it is clear that successful management of these difficult pregnancies requires a team approach involving the patient, family, obstetrician and perinatologist, pediatrician and neonatologist, and ancillary services to provide careful monitoring and counseling in a home or hospital setting.

Dr. Frank Terada, Honolulu, Hawaii. About 2½ years ago we started our in vitro fertilization program in Honolulu. Because the local insurance companies cover only one attempt, we have aimed for a very high level of stimulation with estradiols with doses up to 3000 pg/ml for most patients. In a few cases we had retrievals of 36 and 42 eggs; we do not have a freezing program yet. We have transferred as many as 12 embryos, and as a result we have had a higher number of multiple pregnancies. To date, we have had six quadruplet pregnancies; one started as a quintuplet and had a spontaneous vanishing fetus. All six patients have been sent to California for embryo reduction. Four have already been delivered of twins and two more are carrying twins at this time. All four carried their pregnancies almost to term; the last two pregnancies were carried until 37½ weeks with infants weighing approximately 6½ to 7 pounds each. All pregnancies were rather uncomplicated; one patient flew in from Maui every month for prenatal care. All were delivered by cesarean section, and problems were minimal.

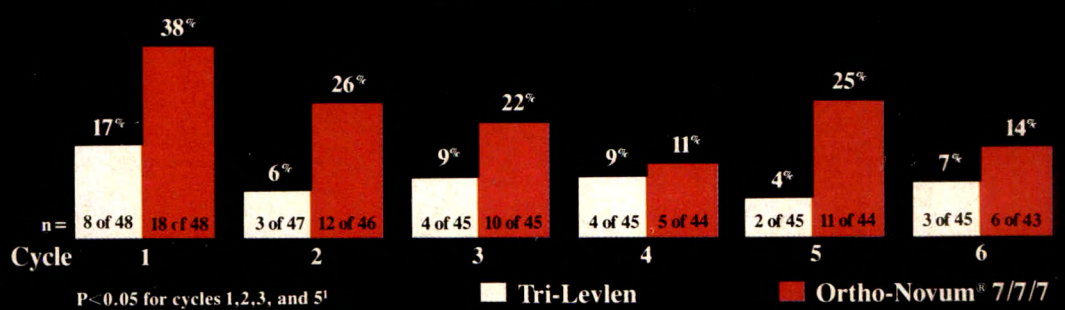
Dr. Charles Plows, Anaheim, California. We thrive on anecdotes in this organization. I am going to tell you about delivering quadruplets 20 years ago in an 0.5 level hospital. The mother was 29 and had not taken any ovulation drug. Because she had no insurance, I did not hospitalize her but I made a house call practically every day during her last few weeks. The hospital, the pediatricians, my associates, and I donated all services. At the time of cesarean section, we tried to identify the placenta for each infant with various clamps on the cords. Of course, once we delivered the infants with all of these clamps, the circulating nurse promptly removed them all. We lost even that little bit of scientific information. We had no α-fetoprotein testing, no ultrasonographic scans, no fetal monitors, just a lot of luck. The patient carried the pregnancy to 37 weeks. According to the findings in this paper, we should have delivered her at 34 weeks. Three of the babies weighed over 4 pounds. The smallest weighed 2 pounds, 14 ounces and did not survive. This was a rather primitive episode by today's standards. Those boys are now 20 years old. I thought you would like to hear that quadruplets could be delivered in a very low level hospital with a reasonable degree of success.

Dr. Simon Henderson, San Francisco, California. When we treat patients with menopausal gonadotropins, we try to retrieve a reasonable number of eggs because our success rate in terms of pregnancies depends on that. This observation has also been made with in vitro fertilization and embryo transfer. Fortunately, only very rarely do all five or six eggs fertilize and implant in the uterus, but there is an increased chance of one or two doing so. Therefore we must realize that multiple pregnancy is a rather rare result of our treatment and that our success depends on producing very few of these multiple pregnancies. In this vein, I do not really see that by improving our ovulation protocols we are going to stop multiple pregnancies from occurring.

I think this is an encouraging study. The outcome of quadruple pregnancies has been extremely good, considering the circumstances. Referring to my own personal experience, I had one quadruplet pregnancy induced with Pergonal. The patient was hospitalized at 14 weeks and was delivered at 35 weeks. She had severe sciatica throughout this period. She did not have premature labor. The infants, all weighing about 4 pounds, were delivered by cesarean section and all did very well. The couple was fairly affluent and had four English nannies to care for the infants.

In light of the findings in this study, I think that we still need to determine whether we should advise patients with quadruplets to have selective termination or to continue their pregnancies. We should give these patients information from this study to help them make this decision.

Dr. Keith Russell, Los Angeles, California. Dr. Collins, I am curious about the one ectopic pregnancy. Were these a quadruple ectopic pregnancy, or one ectopic among four?



Dr. Kenneth Burry, Portland, Oregon. With patient surveys it is very easy to obtain biased data. Patients with good outcomes may respond and those with poor outcomes may not. Because a substantial number of your questionnaires were not returned, how much do you think your data are biased?

Dr. Collins (Closing). Dr. Russell, the ectopic pregnancy that involved one fetus ruptured at 11 weeks. The mother had cerclage at 20 weeks and was delivered of the other three infants at 29 weeks.

Reporting bias is a major limitation of any questionnaire study. Of the women who contacted this organization, however, 63% did so during pregnancy and could be followed up prospectively. The 50 patients who did not return questionnaires were called and follow-up was obtained. There were 50 losses among 200 fetuses, a perinatal mortality rate that is actually lower the one presented for the 71 study pregnancies. Excluding this group would not markedly affect the neonatal or perinatal mortality rates. The questionnaire format, although not ideal, was the most effective way to gather data on this number of quadruplet pregnancies.

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

n = number of women with a bleeding event occurring during a cycle.

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY
Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxy-gon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first mi period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient shou apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the lig these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate for contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no pr information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estr combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogen one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentag patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increas triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of t findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hyperten may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in u and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer expos and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more like develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to nor after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persisten severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changin an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necess since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhe young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuatio OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive metho Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of moth receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatm and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic orga including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 y without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparatio preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed a the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs sho stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patie with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice wh receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Sten hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in su patients. 7. OC users may have disturbances in normal tryptophan metabolism whi may result in a relative pyridoxine deficiency. The clinical significance of this is yet to determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregna woman is predisposed to the development of folate deficiency and the incidence of fola deficiency increases with increasing gestation, it is possible that if a woman becom pregnant shortly after stopping OCs, she may have a greater chance of developing fola deficiency and complications attributed to this deficiency. 9. The pathologist should advised of OC therapy when relevant specimens are submitted. 10. Certain endocrin and liver-function tests and blood components may be affected by estrogen-containi OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and facto VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platel aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circula ing total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin upta is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced respon to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracyclin

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (se "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertensior gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies ar needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/o vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdomina cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and afte treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when give immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, ner vousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradio Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taker later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it unti after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method o contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Breast cancer detection: Experience in a suburban community

John A. Goodno, Jr., MD
Arcadia, California

Six hundred sixty-nine breast biopsies performed at the Methodist Hospital of Southern California and the Arcadia Outpatient Surgery Center during 1987 and 1988 were reviewed. Three hundred twenty-eight biopsies were performed for clinical indications (lump, thickening, or nipple discharge). Three hundred forty-one biopsies (51%) were peformed because of mammographic abnormalities, and required preoperative x-ray localization. Of the 341 localized biopsy specimens, 261 were varieties of fibrocystic mastopathy, fibroadenoma, papilloma, or hyperplasia. An additional 31 cases showed atypical ductal or lobular hyperplasia. One hundred fifty-one breast cancers were detected in this series of 669 breast biopsies. One hundred two (68%) of these were detected as a result of a clinical finding, and 49 were detected as a result of mammographic abnormalities (a 32% incidence of occult breast cancers). Among the 341 x-ray localization biopsies performed, breast cancer was detected in 14%. (AM J OBSTET GYNECOL 1990;162:1393-7.)

Key words: Breast biopsies, mammography, breast cancer, occult breast cancer

Breast cancer is the most common cancer in women[1] and is the leading cause of death from cancer in women age 40 through 49 years.[2] Because early detection dramatically improves long-term survival,[3] the ability to diagnose this disease at an early stage is vital. Increased public awareness and widespread use of mammography have contributed to our ability to diagnose breast cancer earlier. The gradual reduction in radiation exposure to the breast with both film and xeromammography has resulted in more liberal use of screening mammography. Radiation dosage to the breast (expressed as mean glandular dose) is now approximately 0.04 R per film with film screen technique.[4] With the increased use of mammography in breast screening and improved quality, an increasing number of breast cancers are being detected in a nonpalpable stage.

This article reports the retrospective analysis of breast biopsies performed at a suburban community hospital and a freestanding outpatient surgical center during 1987 and 1988.

Material and methods

To ascertain the effectiveness of breast cancer screening in the Arcadia, California community, breast biopsies performed at Methodist Hospital and the Arcadia Outpatient Surgery Center during the years 1987 and 1988 were reviewed. Review of this biopsy material does not include all cases of breast cancer diagnosed in the local area because some patients with abnormal mammograms or clinical findings were referred to centers outside the local area for microscopic diagnosis and definitive treatment. Analysis of this material, however, yields a reasonable indication of the effectiveness of breast cancer screening in this community.

At both the Arcadia Outpatient Surgery Center and the Methodist Hospital of Southern California, biopsies were performed on the basis of clinical findings (lump, thickening, nipple discharge) or mammographic abnormalities. Xeromammography was used more commonly than plain film mammography in this community. Biopsies were performed by general surgeons (n = 18), family practitioners (n = 3), and gynecologists (n = 2).

Biopsies were performed with patients under either general or local anesthesia, depending on the preference of the patient or surgeon and on the clinical situation; often the patient preferred a one-stage frozen section followed by immediate definitive surgical treatment if cancer was found. Suspicious breast lesions detected by mammography were needle localized radiographically and a small amount of methylene blue was injected into the abnormal area. All dye-stained tissue was excised at biopsy. Frozen section or specimen radiography was performed to confirm that the significant radiographic abnormality had indeed been excised.

Results

Table I demonstrates an overall summary of the results of 669 biopsies. Results of 151 breast biopsies revealed cancer; 49 of these lesions were detected by mammography alone and thus were clinically occult (32%).

The age range for patients diagnosed with breast

Table I. Summary of results

Biopsies	669
Breast cancers	151
Occult breast cancers	49 (32%)
Atypical hyperplasias	31
Mammography-generated biopsies	341 (51%)
Percentage of breast cancers in localized biopsies (49/341)	14%
Percentage of breast cancer and atypical hyperplasia in localized biopsies (80/341)	23%

Table II. Age of patient with breast cancer at time of diagnosis

Age group (yr)	*No.*	*%*
30-39	7	5.0
40-49	15	10.0
50-59	29	19.2
60-69	47	31.1
70-79	34	22.5
80-89	17	11.2
90-99	2	1.0

cancer was from 32 to 92 years. The largest number of cancers occurred in the 60 to 69-year-old group. There were 47 cancers (31%) in this age group. Table II shows the incidence of cancer in various age groups.

There was a significantly higher incidence of cancer (27%) in the hospital-performed biopsies compared with a 16% incidence of cancer in the biopsies performed in the Arcadia Outpatient Surgery Center (Table III). This difference presumably represents the surgeons' selection of the hospital environment for biopsy in obvious clinically suspicious lesions when an immediate biopsy, frozen section, and mastectomy sequence might be preferred.

Benign disease was detected in 518 of the 669 biopsy specimens (77%). Included in this category were fibrocystic mastopathy, adenosis, fibroadenoma, papilloma, lipoma, and lobular, and ductal hyperplasia. An important subgroup of benign lesions includes the atypical hyperplasias, both ductal and lobular.

Three hundred forty-one of the 669 biopsies (51%) had preoperative radiographic needle localizations. Forty-nine of the 341 localized lesions were malignant (14%), and if the cases of atypical hyperplasia (31 cases) are included, the incidence of malignant or potentially malignant disease among localization-biopsy procedures is 23% (Table I).

Mammographically localized lesions were categorized as clustered calcifications, mass or asymmetric density, and spiculated mass. Table IV shows the radiographic features of the 49 occult or nonpalpable breast cancers detected in this survey. Clustered calcifications were the most common mammographic finding in these nonpalpable cancers.

Comment

The 32% incidence of clinically occult disease in the Arcadia Breast Cancer Survey is similar to that reported for the Breast Cancer Demonstration Detection Program (BCDDP).[3] It would appear that mammography is detecting approximately one third of breast cancers with current technology, indeed, an important observation.

In this series slightly more than half of the breast biopsies (341 of 669, or 51%) were performed as a result of mammographic abnormality. These 341 radiographic localization procedures resulted in the detection of 49 occult cancers, (14%), compared with reports of 14%, 16%, 29%, and 31% reported in the recent literature.[5-9] The relatively low yield of positive biopsy specimens in this series may have resulted from the nonuniform radiographic facilities, primary care physicians, and surgeons composing this study compared with higher percentage rates reported from more controlled studies in university-type environments.[9] The burden placed on the clinician, radiologist, and patient when a mammographic abnormality is detected is obvious. Only an aggressive approach to biopsy will detect breast cancer early. With the current state of technology, mammography may not always reliably differentiate between benign and malignant lesions.[6] Moskowitz[10] considers a 10% yield of malignancies from radiographically localized biopsies to be acceptable to avoid missing early breast cancer.

Of the localized biopsies, there were 31 in which either ductal or lobular atypical hyperplasia was diagnosed. The addition of these cases of atypical hyperplasia to the 49 occult carcinomas yields a 23% positive rate of malignant or potentially malignant biopsy results. The importance of atypical hyperplasia is emphasized by Page's study[11] showing the subsequent risk of invasive cancer to be four to five times that of the general population in a 17-year follow-up of cases of atypical hyperplasia.

In this series there were four palpable cancers not seen on the mammogram. (Unfortunately, the overall false-negative rate in this study cannot be determined because review of several records in which presence of a lump resulted in biopsy does not indicate that a mammogram was done). A negative mammographic result should not delay biopsy in those patients with a palpable lump or dominant mass, thickening, bloody nipple discharge, or other significant clinical signs because the false-negative rate for mammography may approximate 10%.[12]

No attempt was made to evaluate staging and treat-

ment in this study because a significant number of patients were referred to other treatment centers for definitive surgery, radiation, or chemotherapy. The impressive number of occult or nonpalpable breast cancers detected in this series lends credence to the importance of screening mammography.

The value of screening programs is evidenced by recent analysis of Breast Cancer Demonstration Detection Program data showing 87% and 81% 5- and 8-year survival rates, respectively, for all invasive breast cancers compared with an unscreened group with 74% and 65% rates, respectively, for those cases diagnosed in the National Center Institute Surveillance, Epidemiology and End Results programs. As expected, the highest survival rate occurred in those cases of occult breast cancer detected by mammography only (94%, 8-year survival).[3]

Clinicians should not be lulled into a false sense of security by the fact that the breast cancer was nonpalpable, because the incidence of positive axillary lymph node involvement has been reported as high as 34% in these minimal but invasive breast cancers.[13] However, a small cancer undoubtedly is better than a large one. If mammography results in detection of noninvasive cancers, the 10-year survival rate has been reported to be 100%.[14]

Considering that the doubling time for breast cancer cells may average 100 days, it would require 10 years for a tumor to attain a clinically palpable size of 1 cm.[15] In women with large breasts and a deep tumor, even a 1 cm tumor would be difficult to detect through palpation alone.

Moskowitz[10] estimates that with aggressively performed screening, a mean detection lead time of 2½ to 3½ years may be gained over the usual clinical detection of breast cancer. A recent comparison of palpable and nonpalpable breast cancers by Pagana et al.[16] found that the nonpalpable tumor was more often noninvasive, smaller, and nodal metastasis significantly less frequent. However, the frequency of nodal metastasis was similar when adjusted for size and grade.

If progress in reducing mortality in breast cancer is to continue, it is obvious that clinicians must urge more widespread use of mammography and implement screening recommendations advised by the American Cancer Society. Despite the overwhelming evidence supporting the use of mammography, over 60% of women older than age 50 have not had a mammogram in their lifetime.[17]

The gynecologist's role as a primary care physician in urging patients to perform breast self-examination, obtain a yearly breast examination, and have periodic mammograms is paramount. It behooves the clinican to become very involved in mammographic screening to assure his patients of good quality studies. It is highly desirable for the clinician to review all abnormal mammograms with the radiologist before management decisions with the patient.

Table III. Comparison of biopsies at Methodist Hospital and Arcadia Outpatient Surgery Center

	No.
Biopsies	
Methodist Hospital	371
Arcadia Outpatient Surgery Center	298
Breast cancers	
Methodist Hospital	102 (27% of biopsies)
Arcadia Outpatient Surgery Center	49 (16% of biopsies)
Occult cancers	
Methodist Hospital	31 (30%)
Arcadia Outpatient Surgery Center	18 (37%)

Table IV. Mammographic features of occult malignant lesions

Total occult lesions	*No.*	*%*
Clustered calcifications	20	41
Spiculated mass	12	24
Mass, density, or asymmetric density	17	35
TOTAL	49	100

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. James D. Fearl, Portland, Oregon. Dr. Goodno retrospectively reviewed 2 years of breast biopsy results at a general hospital and an outpatient surgery center in Arcadia, California. Breast lesions were identified about half the time by clinical findings and half by mammographic localization. Confirmation of mammographically identified lesions was done by frozen section or specimen x-ray film. One hundred fifty-one cancers were diagnosed from 669 biopsies. About one third of the cancers were occult lesions identified by mammographic criteria. These 49 occult cancers represented 14% of the 341 localized lesions. If the additional 31 atypical hyperplasias were added to the occult cancers, the total incidence of localization-biopsy procedures was 23%. Clustered calcifications were the most common characterization of nonpalpable lesions.

An apparent goal of this retrospective analysis was to ascertain the effectiveness of breast cancer screening in a local community. To accurately determine the effectiveness would, I think require working through the radiology departments to find the total number of mammograms performed and the number of biopsy specimens obtained elsewhere, as well as at the two institutions studied. The fact that 328 biopsies, which included 102 detected cancers, were done for clinical indications could suggest that mammography was underutilized, since it is not reported how many of these women had prior mammograms.

Although the benign/malignant ratio of 14:100 in this study falls above the stated minimum standard of 1:10, according to Moskowitz,[1] others feel 2:5 is the generally accepted ratio and as high as 1:3 is attainable.[2] The clinical criteria of thickening is likely to have many different meanings to 23 clinicians. I was unable to tell if mammograms were ever used or how often they were used to clarify the indication for biopsy in equivocal clinical findings. I believe the radiographic description of clustered calcifications can also have liberal interpretation. The high incidence of this finding was noted in the occult malignancies but not mentioned in the benign biopsy specimens.

Dr. Goodno, could you give the age distribution of the seven patients in the 30- to 39-year-old group? Were these patients screened for a risk factor or did they have biopsies because of clinical findings? To phrase this question in a politically acceptable way, do you think there was significant variation in interpretation criteria of the involved radiologists? To quote one of your references regarding decision to biopsy, the purpose is to obtain ". . . accurate radiologic criteria for biopsy without a plethora of unnecessary biopsies for suspicious mammographic findings."

Since completing your review and analysis, have you made any major changes in your general attitude toward breast screening or method of evaluating clinical breast findings?

During the last decade, the improvement in mammographic techniques and the increasing popularity of screening mammograms have been significant, but much controversy still remains. Considerable difficulty is described in correlating atypical hyperplasia and mammographic findings.[3] The frequent tendency for multicentric ductal hyperplasia makes mammographically directed biopsies difficult to correlate with mammographic findings. Unfortunately, medicolegal influence has great impact on screening and diagnostic criteria. A wide range of philosophies regarding screening mammograms are described in the literature. Moskowitz[1] thinks excessive claims for accuracy and sensitivity and specificity, particularly in screening, must be avoided. Humphrey and Ballard[4] describe the attributes of a good screening test to include high sensitivity and specificity. Marchant, in discussing breast cancer detection, questions whether sensitivity and specificity have any real meaning, sensitivity being an acquired art and specificity being irrelevant because ". . . when it's high, it's too late."[5]

Numerous studies show improved survival with early detection of breast cancer; however, as shown in the most recent national statistics, there does not appear to be a significant improvement in survival when national age-adjusted cancer death rates are examined.[6] Dr. Goodno quotes a reference that points out that more than 60% of women over age 50 have not even had a mammogram. That same reference mentioned the results of a survey that pointed out that the reason a high proportion of women had not had a mammogram was because their physicians had not recommended one to them. For a screening test to be worthwhile, the disease being screened for, and the screening test itself obviously must have certain characteristics such as low-cost, detectable preclinical phase, and a treatment for the disease must be more effective when applied to screening-detected disease than when applied to the symptom-detected disease. Nevertheless, the early detection efforts must have the enthusiastic support of physicians and be readily accepted by women.

DR. WILLIAM HINDLE, Los Angeles, California. I note that half the biopsies were done because of mammography alone. The management of nonpalpable breast lesions is an entirely new field with which all gynecologists should become familiar. Mammographic accuracy depends on the number of cases seen and the skill of the radiologist reading the films. At the large breast centers in Sweden like the Karolinska Hospital in Stockholm, or similar centers in Falun, Goteborg, and Malmo, the accuracy is excellent. Dr. Tabar in Falun reads 300 mammograms a day (Tabar L. Personal communication, Falun, Sweden, 1989). This amounts to a total of 1200 films, two views for each side. His true-positive rate for the detection of nonpalpable cancer is 90%. In fact, if his pathologist does not find cancer, Dr. Tabar tells him to cut more slides because he "knows" that the cancer is there. In contrast, the minimum true-positive rate accepted by the American College of Radiologists is 10%. That is, of 10 nonpalpable lesions called "probably malignant" on the basis of mammography, one should actually prove to be a cancer. Most U.S. centers report around one cancer per five biopsies.

When we discuss palpable breast lesions, the woman's age becomes critically important. In a recent report of women who had palpable breast masses, Edeiken[1] found that 43% of the cancers were missed by mammography in women under 50 years of age. In women over 50 years, only 12% of lesions were missed by mammography. This is because fat displaces the glandular tissue and there is more mammographic contrast as women grow older. With the denser breasts of younger women, mammographic interpretation is more difficult.

I hope that in the future mammographers here, as in Sweden, will adopt the following interpretations of breast lesions: (1) mammographically malignant, (2) mammographically benign, or (3) mammographically indeterminate. The indeterminate lesions require open biopsy for definitive diagnosis. Swedish physicians have become so accurate with the use of fine-needle aspiration of breast lesions that they now do few open biopsies for diagnosis.

Dr. Goodno, were the in situ cancers included in the "malignancies" in the data you presented? It is unfortunate that the stage of the cancers could not be tabulated. The crux of all of this effort is the ultimate clinical outcome. Given the indolent, insidious nature of breast cancer, it may take more than 20 years to determine the final outcome.

REFERENCE

1. Edeiken S. Mammography in the symptomatic woman. Cancer 1989;63:1412-4.

DR. GAINER PILLSBURY, Long Beach, California. One of the major dilemmas for clinicians who use screening mammography is the report of equivocal or suspicious radiographic findings in the absence of a palpable lesion. To improve accuracy and to diminish the number of unnecessary biopsies, we established a breast evaluation center in the spring of 1988 at Long Beach Memorial Hospital. We have a radiologist on site who reads only mammograms, and use dedicated mammographic equipment capable of magnification, and ultrasonographic equipment to differentiate solid from cystic lesions. We also have well-trained technologists. Between June 1, 1988, and Aug. 15, 1989, we performed 9428 screening mammograms. The films are batch read to reduce the cost. Patients with films that are interpreted as definitely positive have biopsies done. Many patients whose initial films are suspicious or equivocal are scheduled to return for additional studies, including magnification views, ultrasonography, or both. Tissue was obtained in 143 women after these procedures. Of these, 67 lesions were malignant and 76 were benign, a true-positive rate of 47%. These preliminary data support the concept that the use of enhanced imaging techniques and ultrasonography can reduce the incidence of false-positive mammograms and the number of unnecessary biopsies.

DR. ROBERT LOWDEN, Seattle, Washington. I would like to reiterate the statement that you should not trust the radiologist's report of a negative mammogram if you have a palpable mass. It is better to do a biopsy of the lump because otherwise you are going to miss a cancer. A big problem now with litigation is breast cancer missed by a gynecologist.

DR. GOODNO (Closing). Dr. Fearl, we do not have data about the number of screening mammograms performed to yield these mammographic abnormalities. I wish we did. We probably could obtain data concerning the 30- to 39-year-old women but I did not include such data in the study. Most of those lesions were actually palpable lumps rather than radiographic abnormalities. Like Dr. Pillsbury's hospital, we have also established a breast imaging center in Arcadia, which started in July of 1989. The center provides screening films and xerography and ultrasonography for complete evaluation of radiographic abnormalities. Dr. Hindle, in situ carcinomas were included in this study. We did not analyze staging or therapy because many of the patients with cancers identified in this study were referred to other centers—City of Hope, University of California, Los Angeles, Norris Tumor Institute, etc.—for definitive surgery, radiation, or chemotherapy.

Vaginal birth after cesarean or repeat cesarean section: Medical risks or social realities?

E. Paul Kirk, MD, Kathleen A. Doyle, MD, Janet Leigh, MD, and Mary L. Garrard, MSN
Portland, Oregon

Despite the known medical safety and success of vaginal birth after cesarean section, rates of planned repeat cesarean sections remain high. The process involved in women's decisions to choose vaginal birth after cesarean section or repeat cesarean section was investigated by a questionnaire study at a private and a public hospital. Women were questioned regarding timing, influence of others, reasons for their choice, satisfaction with the decision, etc. Results from 160 respondents showed that over half the women identified themselves as the primary decision maker. Physicians exerted more influence on the decisions of patients at the public hospital than on the patients at the private hospital. Overall, social exigencies appeared to play a more important role than an assessment of the medical risks in making these decisions. (AM J OBSTET GYNECOL 1990;162:1398-405.)

Key words: Vaginal birth after cesarean, repeat cesarean section, decision making, informed consent

The obstetric revolution of the last two decades has been characterized by the remarkable results in neonatal intensive care units, particularly with low-birth-weight infants, the development of the specialty of perinatology with the focus on the fetus as the patient, and new imaging and monitoring equipment to sharpen that focus, and the dramatically increased use of cesarean section as a method of delivery. Features of the revolution have included the virtual elimination of birth trauma and intrapartum fetal asphyxia death, decreasing maternal and perinatal mortality, decreasing morbidity from cesarean section, rising health care costs and, inevitably, an increasing number of women who enter the second pregnancy with the physical scars and the mental memories of the previous pregnancy, labor, and delivery.

As this revolution progressed, another revolution was occurring as pregnant women and their advocates in the late 1960s and early 1970s sought to gain more control over their pregnancies. They were anxious to move away from what was seen as the older paternalistic style, often typified by rigid labor practices, standing orders, spinal anesthetics, and elective outlet forceps. The new style was to include more patient autonomy, more flexibility, more expectant management, fewer physical interventions, more effective childbirth preparation, fewer narcotics, and the encouragement of the delivery as a family event with early mother-infant interaction in the neonatal period.

By the late 1970s the trend of the rising cesarean section rate was established and proponents were forecasting a continuing progressive rise.[1] Skeptics doubted that there was any direct relationship between the increased use of cesarean sections and improved perinatal outcome. Experts were called together to halt this trend and to proffer some sound advice regarding the management of abnormal, and therefore difficult labor and the diagnosis of fetal distress. They cautiously suggested that vaginal delivery after a previous transverse, low-segment cesarean section might be safe under certain rigidly controlled conditions.[2] This cautious opinion was based on the limited information available at that time, which implied that these vaginal deliveries carried a much lower risk to mother and fetus than had been assumed by the practice based on Craigin's original threatening dictum: "Once a section—always a section."

The last decade has seen an accumulation of experience and data that fully support the consensus recommendation and studies have shown that the risk of uterine rupture is low.[3-6] Consequently, the risk of fetal injury from uterine rupture is very low and importantly, the probability of vaginal delivery is high: 75% to 80% in those women who attempt vaginal birth after cesarean section. More recent studies have responded to some of the previously unanswered questions regarding the safety of vaginal births after cesarean sections with Pitocin administration, epidural anesthetics,[7] low vertical incisions,[8] "unknown" scars,[9] multiple pregnancies,[10] and breech presentations.[11] As the data have

accumulated, public statements have been less cautious. A recent American College of Obstetricians and Gynecologists committee recommended that "The concept of routine repeat cesarean birth should be replaced by a specific indication for a subsequent abdominal delivery, and in the absence of a contraindication, a woman with one previous cesarean delivery with a low transverse incision should be counseled and encouraged to attempt labor in her current pregnancy."[12] It would seem that these good results would correspond with the more autonomous style of management of a subsequent pregnancy and that the prospects of a safe delivery, with a good probability of avoiding another abdominal incision, would be enticing.

The national experience does not support this assumption. A recent survey published in 1987 showed that 92% of women with a history of previous cesarean sections are delivered by repeat elective surgery and in 50% of the nation's hospitals, a vaginal birth after cesarean section has never been attempted.[13]

It is not clear who makes the decision to avoid vaginal births after cesarean section, and why those decisions are made when the clinical data now available would support a much more optimistic approach. In an attempt to understand some of the issues in this clinical management decision, a questionnaire study was undertaken.

Material and methods

The study was conducted at two hospitals in the Portland, Oregon metropolitan area: University Hospital (hospital A) and Good Samaritan Hospital (hospital B). Questionnaires were issued to all patients who were delivered of infants between Dec. 1, 1988, and June 30, 1989, who had a history of cesarean section in any of their previous pregnancies. The questionnaires were issued during the postpartum hospital stay; if they were not completed by the time the patient was discharged, one further attempt was made by mail at a later time to have the questionnaire completed. The questionnaires were designed to describe the ethnic and educational characteristics of the different hospital populations. Separate questionnaires were used for those patients who planned a vaginal birth after cesarean section and for those who chose repeat cesarean section. The questions attempted to identify the patient's perceptions with regard to the management decision and the factors that affected that decision. The answers were collated and comparisons were made between hospital A and hospital B, and between those who chose vaginal birth after cesarean section and those who chose repeat cesarean section.

Results

Two hundred fifty-seven questionnaires were distributed; 160 (62%) were returned. Patients planning a vaginal birth after cesarean section at hospital B were more likely to return the questionnaire (73%) than the repeat cesarean section group (47%) (overall return rate from hospital B, 59%). The return rates for vaginal birth after cesarean section and repeat cesarean section groups were virtually identical at hospital A (66% versus 61%); the overall return rate was 65%. At hospital A there was a total of 1480 births with 265 cesarean sections; the cesarean section rate was 17.8% (14.8% primary, 3% repeat). At hospital B there were 1245 births; the cesarean section rate was 19%, (13.6% primary, 5.4% repeat).

The average age of the patient with a vaginal birth after cesarean section was 27.6 years (range, 17 to 41 years), and for the repeat cesarean section group, 30.6 years (range, 18 to 42 years). Ninety-one percent were married or identified a steady partner. Hospital B respondents tended to have a higher educational level, with 69% of hospital B versus 47% of hospital A patients having some college or a college degree; 19% and 5% of hospital B and hospital A patients, respectively, had a professional degree. Eighty percent of patients from hospital A were white; the remainder came from a variety of minority backgrounds. All but one patient from hospital B were white.

Eighty-four percent of patients at hospital A had had their prenatal care at a resident or county clinic, with only half attending for their first prenatal visit in the

first trimester. At hospital B, 95% of the prenatal care was in a private office, and 90% of the first visits were in the first trimester.

The responses to the question regarding reasons women chose vaginal birth after cesarean section are summarized in Table I. Half the patients were aware of vaginal birth after cesarean section as an option before conception (Table II). The patients from hospital A had no clear pattern in the timing of the decision, whereas patients at hospital B tended to make the decision for vaginal birth after cesarean section early in pregnancy and for repeat cesarean section, late in pregnancy (Table III).

The patient's reason(s) for choosing an elective repeat cesarean section are listed in Table IV. The patient's perceptions of her chances of vaginal delivery are shown in Table V. The majority of patients identified themselves as the decision maker either alone (55%) or in conjunction with the physician (34%), although the physician alone was identified as the decision maker in 11% of hospital A vaginal births after cesarean sections, and 33% of hospital A repeat cesarean sections (Table VI). The patient's perceptions of the physician's attitude toward vaginal birth after cesarean section are listed in Table VII. Even though the patient perceived herself as being the primary decision maker, 64% and 46%, respectively, identified the physician and the husband or partner as having "a lot" of influence on the decision. "Others" (friends, parents, siblings, nurses, childbirth educators) were more likely to influence the decision when a vaginal birth after cesarean section was chosen. This difference was more obvious with patients from hospital A (Table VIII); physician influence was stronger at hospital A than at hospital B: 69% of patients at hospital A versus 59% of patients at hospital B stated their physicians had "a lot" of influence. In the 25 patients who had a repeat cesarean section after a failed vaginal birth after cesarean section, 52% were for management of failure to progress and 40% were for management of fetal distress. Of those 25, 48% said that they would never try vaginal birth after cesarean section again, whereas 20% said that they would definitely try again. Only 27% of patients planning a vaginal birth after cesarean section and 20% of repeat cesarean section patients attended a prenatal class. Patients from hospital B were more

likely to attend prenatal classes than those from hospital A (34% vs 17%).

Comment

Although there has been extensive discussion of the lack of necessity to perform a repeat cesarean section in the light of the proven safety of vaginal birth after cesarean section, only 8% of women in the nationwide survey underwent a trial of labor in 1984. The likelihood of a trial increased with the size of the obstetric service, and it is likely that some of the reluctance to permit a trial may be related to the availability of emergency services, although it is important to note that other intrapartum catastrophes occur more frequently than uterine rupture.[14]

Even on larger obstetric services, the rates of vaginal birth after cesarean section did not exceed 25%, and there is uncertainty whether this is because the physicians do not allow trials of labor, or that mothers do not want to experience them. Within the admitted limitations of a questionnaire study, some patterns appear to emerge. Both hospitals in the study have a relatively low cesarean section rate by modern standards, and each promotes vaginal birth after cesarean section. The population in hospital B is almost exclusively white, better educated, and receives prenatal care early through private physician offices. At hospital A, the population is ethnically heterogeneous, is less well educated, and is likely to receive prenatal care later from a variety of providers in different settings, most of whom would not provide longitudinal care through delivery. In general, women from hospital B gave better defined opinions (Table IV), and the *troika* of the patient, partner, and physician seemed more important (Table VI). They tended to make the decision for vaginal birth after cesarean section earlier in the pregnancy but left the decision for a repeat cesarean section later. Both groups were reasonably well informed about vaginal birth after cesarean section, but their information was not always accurate. The women who chose repeat cesarean section were particularly pessimistic about their chances of a vaginal delivery, which was almost certainly a factor in the management decision. The patients from hospital A, who were relying on the physician, were more likely to receive information and support from other health care providers, family, and friends. The better educated group did not appear more interested in or more likely to choose vaginal birth after cesarean section, as has been previously reported by McClain.[15] The reasons for choosing vaginal birth after cesarean section (recovery period, wanting the experience) and for choosing repeat cesarean section (knowing what to expect, avoiding the pain of labor, convenience, and timing) confirmed the social rather than the medical model of the decision making. The exception to this was "the belief that the chance of vaginal delivery was poor," which is a misappreciation of the medical probability rather than an appreciation.

Although there are extensive reports in the literature

that analyze the factors that affect the cesarean section rates in various settings,[16, 17] and various descriptions of policy that have successfully reduced the cesarean section rates,[18, 19] there is little information about the decision-making process in individual cases. Through a series of structured interviews of 100 patients, McClain[15] emphasized that all women made choices that were shaped by social exigencies and constraints, and that none engaged in probabilistic evaluation of medical risk, choosing instead to develop negotiation strategies that would enhance control of uncertainties, such as the length and pain of labor.

In this study, although the physicians were identified as an important part of the decision-making process, patients in hospital A were not always able to identify what the physicians' attitudes were, possibly because of the lack of longitudinal care. Clearly, decisions are made either in favor of vaginal birth after cesarean section or repeat cesarean section, and this study raises questions about the nature of informed consent.[20] Ten years ago when vaginal birth after cesarean section was considered unsafe and 98% of women had repeat cesarean sections on the basis of the physician's concern for the risks of uterine rupture, the consent was, in a sense, uninformed because it reflected old data. It now appears that many women choose repeat cesarean section, an equally uninformed choice when assessed from the point of view of medical risk, but one that makes social sense because it respects individual preference. It appears that physicians are likely to collude with this choice, perhaps out of respect for patient autonomy, a reluctance to change long-held positions, a wish to avoid a failed vaginal birth after cesarean section in up to 25% of cases, or fear of litigation.

It is not possible to determine how well patients were informed in this study, nor how free was their consent. Seventy-three percent of patients who had a repeat cesarean section reported that their physicians either discouraged vaginal birth after cesarean section or had either neutral or unknown attitudes, although 26% chose to have a repeat cesarean section despite the physician's encouragement of vaginal birth after cesarean section. This in turn raises the question: Should the decision be simply the choice of the patient, a truly elective repeat cesarean section? By means of a mathematic probabilistic model, Feldman and Freeman[21] made a cogent argument for the consideration of prophylactic cesarean section at term in all pregnancies. An essential part of that argument was the significantly reduced maternal risk of elective cesarean section. Coupled with the lack of any convincing evidence that properly consented elective cesarean sections cause any prolonged postpartum depression or maternal infant interaction difficulties, the elective cesarean section appears to be a reasonable choice.

Two ethical considerations remain. First, how far should the obstetric community control individual decisions within the context of increasing costs, limited resources, widespread pregnancy indigency, and managed health care programs? It is clear that clinicians do not practice in a vacuum; whenever a decision is made to perform a cesarean section, it affects the total pattern of obstetric practice, which in turn affects the standard of care. Second, should the patient be free to make a choice for repeat cesarean section? If it is reasonable for her to make that choice in the setting under discussion, then it is neither reasonable nor logical to deny that choice to a woman who does not have a history of a previous cesarean section.

Obstetricians are concerned with balancing freedom

of individual decision making by the patient, with a desire to avoid unnecessary cesarean sections. Truly informed consent can only be provided when the patients understand the medical probabilities, and the physicians understand the social influences and the stepwise process that most patients appear to use in making a decision regarding a vaginal birth after cesarean section or a repeat cesarean section.

It may be that our understanding of the social issues would improve if the counseling commenced in the immediate postpartum period after the *primary* cesarean section. Perhaps parenting classes could be used to "debrief" patients and their families; physicians who are better informed about the patient's social reasoning would feel more confident in negotiating a management that pays more attention to medical probability.

There are obvious drawbacks to this type of study. The conclusions have not been submitted to detailed statistical analysis because of the 62% return rate on the original questionnaires. The described perceptions and trends in the responses would suggest that although the physician has a central role in the decision-making process, we have yet not found a successful way to advocate vaginal birth after cesarean section as we have for vaginal delivery in many other clinical settings.

Discussion

DR. JAMES C. CAILLOUETTE, Pasadena, California. The author has contributed to a large body of literature published during the last decade on the subject of vaginal birth after cesarean section. Despite continued recommendations in support of vaginal birth after cesarean section, the rate of cesarean sections has increased. To better understand the dynamics of this issue, a search of the literature was conducted. What we may be surprised to learn is that obstetricians are *not* searching for ways to avoid a cesarean section, rather they are looking for reasons *for* doing a cesarean section. The following data support this presumption.

The World Health Organization has estimated that approximately 500,000 women die each year from pregnancy-related causes.[1] More than 98% of these deaths occur in developing countries where vaginal delivery is the rule. Maternal mortality rates in these countries are as much as 100 times higher than those in industrialized countries. The stated most common causes of death are obstructed labor and ruptured uterus, postpartum hemorrhage, eclampsia, infection, and complications of illegal abortion.

In a review article in 1987, Petitti[2] stated that, "Beginning in 1969 and continuing through 1983 there was a sharp decline in fetal mortality. Starting in 1969, the positive factors have been family planning, availability of abortion, Medicaid, neonatal intensive care units, electronic fetal monitoring and finally the rising cesarean section rate."

In 1988 the late John Figgs Jewett coauthored a paper entitled "Cesarean section-related maternal mortality in Massachusetts from 1954 to 1985."[3] The paper reports that "The cesarean section delivery rate in-

creased from about 5% in 1954 to 23% in 1984. From 1976 to 1984 the rate of maternal deaths directly related to cesareans section delivery remained essentially unchanged at 5.8/100,000 cesareans as compared to 10.8 maternal deaths per 100,000 vaginal deliveries." This is clear evidence supporting the safety of cesarean section over vaginal delivery in contemporary obstetrics.

To further understand the mind-set of today's obstetricians, a few medical-legal facts should be considered. In a National Institutes of Health publication on cesarean childbirth published in 1980, the subject of litigation was considered.[4] The report states that "Ninety percent of all obstetrical malpractice cases fall into two categories: failure to perform a cesarean delivery and improper use of forceps during delivery."

A recent issue of *Time* magazine on the subject of doctors and patients reported that "In 1988, for the first time in more than a decade, medical malpractice suits abated. Claims settlements were down $100 million from the 1987 high of $4.2 billion."[5] I am concerned that those who discuss the economics of vaginal birth after cesarean section never discuss the economics of litigation. The article further stated that "Nearly one quarter of all U.S. births are currently by cesarean section, which can be less risky to the baby than vaginal delivery and makes the doctor less vulnerable in court." When a popular weekly magazine expresses such a clear view of cesarean delivery, is it so difficult to understand the mind-set of today's obstetricians?

If reasonable people can agree that malpractice litigation is based on the presumption of a bad outcome, and if it is reasonable to agree that physicians strive for a good outcome, then safe medical practice becomes the issue.

This returns us to the issue of vaginal birth after cesarean section. The literature is filled with articles stating that vaginal birth after cesarean section is safe, successful in many cases and should be encouraged, yet it is still not embraced.

In a 1988 article titled, "A successful program to lower the cesarean-section rates," the program was not as successful as stated.[6] Myers and Gleicher[6] reported a 6.25% fetal mortality rate among 48 infants who were breech deliveries with vaginal birth after cesarean section, a sixfold increase over the national average of 1.06%. In addition, their 5-minute Apgar scores below 7 increased significantly from 3.0% to 4.9%, clearly not a success for vaginal birth after cesarean section.

After considering Dr. Kirk's paper, which encourages an increased attempt at vaginal birth after cesarean section, let us consider a different philosophy. Feldman and Freiman[7] have contributed a thought-provoking article titled "Prophylactic cesarean section at term."[7] The authors explored a number of questions asked by a plaintiff's lawyer. The final question was: "Don't you think a mother has the right to assume the extra risks of cesarean section for the sake of her unborn if she wishes to?" After citing many of the risks of vaginal delivery, the authors concluded with four important questions: "In the light of all these considerations, is it tenable for us to continue to fail to inform patients explicitly of the very real risks associated with the passive anticipation of vaginal delivery after fetal maturity has been reached? If an informed patient opts for prophylactic cesarean section at term, can it be denied? If a patient considers the procedure and decides against it, must she then be required to sign a consent form for the attempt at vaginal delivery? Has something important been overlooked?"

I began my resident training at LAC/USC Medical Center 34 years ago. There were 12 obstetrics-gynecology residents, and only a volunteer clinical attending staff. We delivered approximately 1000 infants each month and our cesarean section rate was less than 4%. I regret not performing a cesarean in more cases that it is comfortable for me to recall. Valuable lessons were learned at the great expense of patient health and safety. These are lessons that few residents today have occasion to learn. During my training and after 30 years in private practice, I cannot recall a single cesarean that I regret having performed. However, there have been a number of occasions when I regretted a vaginal delivery.

With clear evidence that the increase in cesarean sections has resulted in improved outcome, and since vaginal birth after cesarean section is associated with the risk of a bad outcome, would the author address the following questions? First, is the increase in the cesarean section rate in industrialized countries an attempt to achieve the perfect outcome? And second, since university hospitals and private hospitals have different populations and different outcomes, is not the difference of opinion and practice between academicians and clinicians to be expected?

Dr. Leroy Casperson, Portland, Oregon. I went back to the archives after I saw this article in the program. My first patient with a vaginal birth after cesarean section was in 1963. From that time I have generally given the patient the option of a vaginal delivery or a repeat cesarean section. I have no statistics, but I have been impressed by how frequently the vaginally deliv-

ered baby was larger than the baby previously delivered by cesarean section for "cephalopelvic disproportion." The current terminology, *failure to progress*, is more accurate and an improvement.

When things go well for a long period, we can become blasé over possible complications that we have been warned to anticipate. The admonitions against induction, augmentation, use of epidural anesthesia, etc. are now frequently ignored. We treat many of these women like any other multiparous patient. Approximately 6 weeks ago I cared for a patient of my associate. Her first delivery was by cesarean section because of herpes. Her surgery and recovery were uncomplicated. She entered the hospital at term in early labor and was given an epidural and Pitocin augmentation after many hours of slow progress. At a 2+ station, after a failed manual rotation, I applied Kielland's forceps but was not able to rotate from right occipitoposterior presentation nor affect descent. I decided to do a cesarean section. When the peritoneum was opened, I saw flecks of meconium floating beneath and edematous vesicouterine plica. Beneath this was a total dehiscence of the previous transverse scar with the shoulder partially extruding. With difficulty, I could reach my hand alongside the head to disengage it. A 10 pound, 13 ounce girl with Apgar scores of 3 and 9 was then delivered. There was a T-shaped vertical extension toward the cervix, which I may have created manually because of the extreme thinness of the lower segment. The defects were repaired and she recovered uneventfully. In retrospect, I could identify two episodes of variable decelerations about the time of complete dilatation and the patient said she felt a sharp pain in the right lower quadrant then. Only these two events suggest when the rupture might have occurred.

Dr. Robert Goodlin, Denver, Colorado. The term vaginal birth after cesarean section was coined in Denver and vaginal births after cesarean sections are popular. In 1989 we had six cases in which the fetus was extruded through the uterine defect. The mothers were all in labor and all had low transverse scars. In two cases in which the patients had epidural anesthesia, the only sign of this problem was severe fetal distress. We wonder now if we should not return to having an operating room available for cases of vaginal birth after cesarean section. That was the case 25 years ago, but we have moved away from this idea. However, in both cases in our hospital, the house officers delivered the fetus within 6 minutes and the infants had good Apgar scores and cord pHs. I do think that we have been too casual about the problem of uterine rupture in vaginal birth after cesarean section.

Dr. Kirk (Closing). Dr. Caillouette, maternal mortality in underdeveloped countries is not the issue here. Cesarean sections are badly needed in underdeveloped countries; they do not have proper access to cesarean section. The issue is not decision making or indications for cesarean sections, it is access. I think this is one of the few topics that we cannot learn from medicine in underdeveloped countries. Your comments about Dr. Meyers' paper, I think, are fair but I will point out with respect that Dr. Meyers' three breech infants who were lost were all in mothers without uterine scars. Their paper introduced a system for critical evaluation of all indications of cesarean sections. Those three breech deaths raise questions about the management of breech presentations, but not about vaginal birth after cesarean section.

Of course, Dr. Goodlin, there is a risk involved with uterine ruptures whenever there is a scar in the uterus. I emphasized that it is important to keep that risk in perspective and I think we have not done this. We have tended to overemphasize the risk of uterine rupture but underemphasize the other risks that exist in difficult labors—cord prolapse, placentae abruptio, fetal distress, and difficult deliveries. I asked questions about indicated cesarean sections. What are the indications for repeat cesarean section and what are the social influences that are affecting these decisions?

Dr. Caillouette asked two questions: Are we in search of perfection? Are the university hospitals and the private hospitals different? The answer to the first question is yes, but we are far from reaching it and we are being ingenuous if we think we will find perfection by being uncritical about the indications for cesarean section. With regard to the second question, our patient populations are different, but surely clinical judgment and intellectual curiosity are prerequisites for both the community and the academic obstetrician.

I think we could learn from Inspector Clousseau of the Pink Panther movies that it is important to ask the right question and to ask it in the right way. You may recall that when Inspector Clousseau went into an inn and saw a dog lying on the floor, he said to the innkeeper "Monsieur, does your dog bite?" The innkeeper said "No." So Inspector Clousseau went up and patted the dog. The dog immediately bit him. Indignantly, Inspector Clousseau said, "But you said your dog didn't bite." And the innkeeper of course said, "Monsieur, that is not *my* dog."

Stage IA_2 squamous carcinoma of the cervix: Difficult diagnosis and therapeutic dilemma

Benjamin E. Greer, MD, David C. Figge, MD, Hisham K. Tamimi, MD, Joanna M. Cain, MD, and Roger B. Lee, MD
Seattle, Washington

The International Federation of Gynecology and Obstetrics instituted a change in the classification for carcinoma of the cervix with a new substage IA_2. The criteria for this substage exceed the generally accepted criteria for microinvasion. Fifty patients with early invasive squamous cell carcinoma of the cervix were treated from 1976 through 1983 with a cone biopsy followed by a radical hysterectomy and pelvic lymph node dissection. These patients were reviewed to evaluate the ability to make the histologic diagnosis and to examine the natural history of the disease with maximal treatment. Histologically positive margins were found at the time of cone biopsy in 66% (33/50) of the patients. Negative margins at the time of cone biopsy were identified in 34% (17/50) of the patients. Residual invasive disease at the time of radical hysterectomy was found in 24% (4/17) of the patients with negative margins. Two of the 50 patients had positive lymph nodes. Three patients had recurrent metastatic disease. This study demonstrates that a preoperative diagnosis of stage IA_2 invasive squamous cell carcinoma of the cervix is a difficult diagnosis to establish and creates a therapeutic dilemma regarding treatment. (Am J Obstet Gynecol 1990;132:1406-11.)

Key words: Stage IA_2 squamous carcinoma of cervix, microinvasion

The concept of microinvasive carcinoma of the cervix as a distinct clinical entity was introduced in 1947.[1] The International Federation of Gynecology and Obstetrics (FIGO) in 1961 defined stage IA carcinoma of the cervix as early stromal invasion. In the early 1970s FIGO defined stage IA as microinvasive carcinoma but failed to provide guidelines for establishing the histologic diagnosis. In 1974 the Society of Gynecologic Oncology (SGO) provided the working definition: a microinvasive lesion is one in which neoplastic epithelium invades the stroma in one or more places to a depth of 3 mm or less below the base of the epithelium, and in which lymphatic or blood vessel involvement is not demonstrated. These histologic criteria have been generally accepted in the United States.

The Oncology Committtee of the FIGO recently mandated changes in the definition of stage IA carcinoma of the cervix.[2] Stage IA carcinoma of the cervix is subdivided into stage IA_1 and stage IA_2. Stage IA_1 is defined as minimally microscopically evident stromal invasion. This includes only those patients with minute foci of invasion visible only microscopically and not penetrating more than 1 mm below the basement membrane. Stage IA_2 is defined as lesions detected microscopically that can be measured. The upper limit of measurement must not exceed a depth of invasion of more than 5 mm taken from the basement membrane, either surface or glandular, from where it originates; and a second dimension, the horizontal spread, must not exceed 7 mm. Vascular involvement, either venous or lymphatic, should not alter the staging. The committee suggested that the diagnosis should be made on microscopic examination of removed tissue, preferably obtained by conization of the cervix, which should include the entire lesion. The criteria for the newly defined stage IA_2 therefore clearly exceed the criteria for microinvasion as defined by the SGO.

Current practice emphasizes the use of colposcopy in the diagnosis of preinvasive and invasive carcinomas. Conization of the cervix is reserved for distinguishing between microinvasion and true invasive carcinoma or those cases with positive endocervical curettage, discrepancy between cytology and biopsy, or unsatisfactory colposcopy results. In certain cases it may serve as a therapeutic modality. We have two major reservations concerning the new definition estalished by the FIGO. One is that it may be a difficult diagnosis to establish even with conization of the cervix. Our second concern is that since the stage IA_2 clearly exceeds the generally accepted definition as established by the SGO, there must be two separate treatment regimens for patients

with a diagnosis of stage IA_2 cervical carcinoma. Traditionally stage IA carcinoma of the cervix has implied conservative surgery, such as cone biopsy or simple extrafascial hysterectomy. Therapy decisions regarding stage IA_2 without a clear understanding of the fine points of the definition may result in undertreatment of patients because the scope of the definition clearly exceeds the currently accepted criteria for conservative surgery.

This study was conducted to evaluate the ability to establish the histologic diagnosis of stage IA_2 by conization of the cervix and to evaluate the natural history and results of a group of patients with early invasive squamous cell carcinoma of the cervix with maximal treatment.

Material and methods

From 1976 through 1983 the Division of Gynecologic Oncology at the University of Washington Medical Center treated 50 patients with early invasive squamous cell carcinoma of the cervix in which a radical hysterectomy and pelvic lymph node dissection had been preceded by conization biopsy of the cervix. The clincial record and pathologic reports were reviewed on each patient. The patient's age, race, parity, initial cytologic results, presence or absence of gross lesions, whether the patient had colposcopy, and if so the outcome and adequacy of the examination, and the diagnosis on directed biopsies were recorded. The pathologic condition of the cone biopsy specimens was evaluated for positive or negative margins, depth of invasion, capillary-like space invasion, multifocal disease, and confluence. The horizontal spread of the tumors was not measured. The pathologic condition of each radical hysterectomy specimen was examined for residual disease after conization, extension beyond the cervix, and site and number of metastatic lymph nodes. A period of at least 5 years has elapsed since the treatment of each patient. The disease status, site of recurrence, subsequent treatments, and outcomes were recorded.

Results

The mean age of the 50 patients was 37 years (range, 22 to 72 years). The mean parity was 2.8. Forty-two of the patients were white and two each of native American, Oriental, black, and Mexican-American background.

Routine periodic screening was responsible for alerting the physician to the diagnosis in all but one instance. This patient had postmenopausal bleeding and an endocervical curettage demonstrated carcinoma in situ. In review, six other patients had a history of vaginal spotting. Forty-nine of the patients had cytologic studies performed at the initial examination. The Papanicolaou smears suggested carcinoma in situ in 22 patients and invasive cancer in 16. The cytologic condition was reported as merely "atypical" in 10 patients, 20% of the total group. One patient had a negative smear but a gross lesion. No visible lesion was present in 94% (47/50) of the patients. In the three patients with gross lesions, two had cone biopsy and the remaining patient had colposcopy and a biopsy consistent with carcinoma in situ but with questionable invasion.

Colposcopy was performed in 70% (35/50) of the women. Twenty-three of the examinations were considered adequate. The indications to proceed with conization of the cervix were based on a question of invasion in 15 patients, carcinoma in situ in six patients, and cervical intraepithelial neoplasia with a positive endocervical curettage in two patients. Twelve of the 35 patients undergoing colposcopy were considered to have inadequate examinations. Eight of those 12 patients had a biopsy diagnosis of carcinoma in situ. Four of the patients did not have biopsies and had conization of the cervix. Conization of the cervix without colposcopy was performed in 30% (15/50) of patients.

The cone biopsies were all performed by referring physicians, and the pathologic reports were reviewed at the University of Washington Medical Center. Positive margins for neoplasia on the cone were present in 66% (33/50) with invasive disease. Twenty-seven of those patients had residual carcinoma at the time of radical hysterectomy and pelvic lymph node dissection. Six of those 27 patients had only residual carcinoma in situ. There were six patients with positive margins at the time of conization of the cervix that revealed no evidence of residual disease at time of radical operation.

Negative margins on the conization specimen were confirmed in 17 of the 50 cases (34%). This represents a group of patients who would qualify as stage IA_2 carcinoma. Four of the 17 (24%) had residual invasive disease at the time of radical hysterectomy despite the negative margins on the cone biopsy specimen. Two additional patients had residual carcinoma in situ.

Capillary-like space invasion was demonstrated in 32% (16/50) of the conization specimens, multifocal invasion in 12% (6/50), and confluence was evident in 48% (24/50). Of the three patients with recurrent invasive carcinoma, one had all three other factors present, one had only confluence, and one was without any factors. No conclusion can be drawn from these findings.

Two patients had evidence of positive metastatic disease in the lymph nodes. One patient with a positive right common iliac node had a 2.2 mm invasive lesion with confluence on cone biopsy with negative margins and no residual cancer at the time of radical hysterectomy. The patient was treated postoperatively with radiation therapy of 5000 cGy to the whole pelvis and

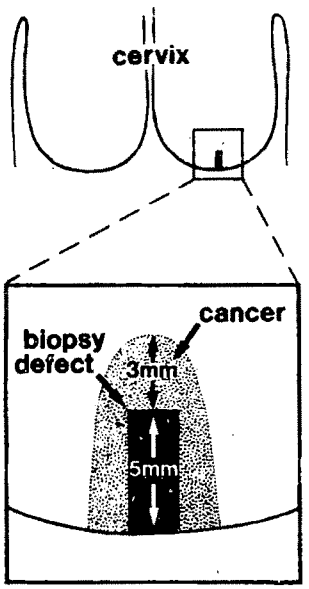

Fig. 1. This figure demonstrates the alteration in the depth of invasion after a cervical biopsy.

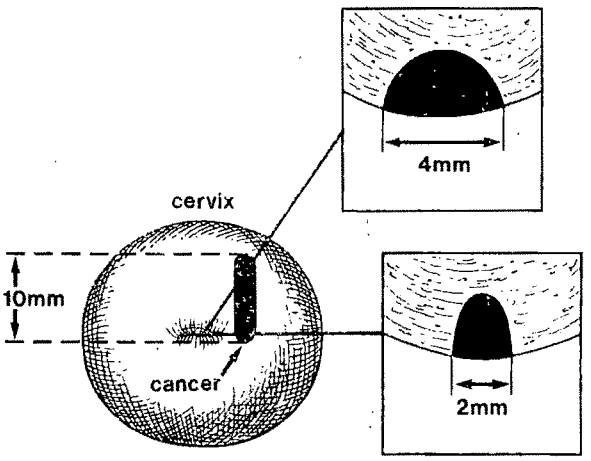

Fig. 2. The maximal horizontal spread of this cancer would not be demonstrated as a result of the radial histologic sections.

4500 cGy to the paraaortic lymph nodes to an upper border of T12. She is alive and free of disease at 87 months. The other patient is dead of disease despite postoperative radiation therapy.

Ninety-two percent (46/50) of the patients had follow-up. Forty-three of these 46 patients were followed up for more than 5 years. The range was from 8 to 123 months (mean follow-up, 68.3 months). There were four patients lost to follow-up in the immediate postoperative period when the patients returned to their referring community.

Four recurrences developed after treatment. One patient had carcinoma in situ at the apex and was treated successfully with an upper vaginectomy. Three patients recurred with invasive disease. One patient had recurrence both in the pelvis and liver at 25 months. The patient underwent palliative radiation therapy and chemotherapy and survived an additional 7 months. One of the patients had a positive left external iliac node and received 5000 cGy to the whole pelvis postoperatively and disease recurred 3 months later. She survived 3 months with additional treatment. One patient had recurrence of disease in the pelvis at 61 months after radical surgery. The patient underwent radiation therapy for the recurrence with whole pelvic external radiation and intraoperative electron beam therapy. Currently she is alive with disease.

Postoperative radiation therapy was administered to four patients. Two patients had positive lymph nodes; one of these patients is clinically without evidence of disease and one is dead of disease. Two patients had extension beyond the cervix on final pathologic review and received adjuvant whole pelvis radiation therapy. Both are clinically without evidence of disease. Two additional patients received radiation therapy for recurrent disease.

Comment

The new FIGO definition of stage IA_2 disease presumably evolved from the volumetric concepts of microinvasive disease.[3] These volumetric concepts have merit in a reserach setting but are impractical for clinical practice. The planar definition of the 5 mm depth of invasion and 7 mm of horizontal spread as adapted by FIGO was made without data to support its utilization.

A presumptive diagnosis of stage IA_2 carcinoma by cone biopsy of the cervix was possible in only 34% (17/50) of cases with early invasive carcinoma in this series of patients. Twenty-four percent (4/17) of these cases had residual cancer in the surgical specimen at the time of radial hysterectomy despite apparently negative margins at the time of the cone biopsy. One patient with 2.2 mm of invasion with negative margins had a positive common iliac node. The diagnosis of stage IA_2 disease becomes untenable if the lesion extends to or beyond the limits of the cone biopsy. This occurred in two thirds (33/50) of the cases of early carcinoma in this study. In such instances, it is customary to proceed with radical surgery because of the unknown depth of residual carcinoma. Although the diagnosis in each instance was established by cone biopsy, only 26% (13/50) of the cases of early carcinoma in this series could be appropriately considered as stage IA_2 lesions. The validity of such a staging classification must be open to challenge.

We can perceive two other major pitfalls in reaching the diagnosis of stage IA_2 carcinoma. Colposcopy and directed biopsy are integral steps in establishing the diagnosis of invasive cancer, and failure of the clinician to avail himself or herself of this approach would be widely criticized. Colposcopic biopsies were performed in 64% of the patients in this series. In each instance, the biopsy presumably removed part of the lesion and therefore may have altered the depth of invasion as seen on the final cone biopsy. This is illustrated in Fig. 1. The validity of a diagnosis of stage IA_2 carcinoma in any case when directed biopsies had encroached on the lesion in question could be justifiably rejected.

A second criticism involves the accepted techniques of pathologic study. Cone biopsy specimens, after initial fixation in formalin, are divided into quadrants and step-sectioned. The maximal extent of horizontal spread could be underestimated by this procedure. Fig. 2 demonstrates a narrow, long circumferential lesion in which the maximal horizontal spread would not be reflected by the histologic condition of the cone. The increasing use of laser conization of the cervix, with its attendant coagulation artifact that may obscure margins and depth of invasion, can only add to the difficulty of making a diagnosis.

The 4% incidence of metastatic lymph nodes and the 6% recurrence rate of invasive carcinoma in this series of cases with early invasive cancer emphasize the necessity of establishing guidelines for therapy. Unfortunately, there are too few patients in this series who "fit" the criteria for either the FIGO or SGO definition of microinvasion to make any conclusions or statements. Recent articles support the SGO definition for microinvasion.[4-7] Rarely patients with metastatic lesions have been reported with <3 mm of invasive cancer.[8] This was demonstrated in this series. Recently, the argument was advanced that guidelines advanced by the SGO may result in unnecessary radical surgery.[9] A more logical perspective is to consider the potential number of failures in the patients that exceed the SGO definition of microinvasion and still meet the criteria for stage IA_2 by the new FIGO definition. A recent paper summarizing reports in the literature concluded that the risk of metastatic disease in the lymph nodes in cases with <3 mm invasion does not exceed 1%.[5] Lesions with a depth of invasion between 3.1 and 5 mm have a nodal metastasis rate of 8%. The difference is highly statistically significant ($p < 0.001$). It would be unconscionable to accept this potential failure rate merely to reduce the number of radical hysterectomies performed for this disease. The literature does not provide clear direction concerning the issues of patterns of invasion, capillary-like space invasion, or horizontal spread.

A clear understanding of the problems in making a diagnosis and the implications of the histologic findings will permit experienced clinicians to make appropriate choices of treatment for their patients. Clinical staging has two purposes: it describes firm criteria that permit comparison of data and it establishes guidelines for treatment. The FIGO classification for stage IA_2 lesions would appear to adequately serve neither purpose. By contrast, the SGO definition for microinvasion serves a practical purpose, and conservative treatment in cases so defined will result in a cure in virtually all instances. Radical hysterectomy and pelvic lymph node dissection should be mandated for patients whose histologic findings exceed the SGO definition for microinvasion. This approach provides the maximum opportunity for cure of invasive cancer. At the next FIGO meeting the current definition of stage IA_2 should be reevaluated and modified to meet the requirements of clinical practice.

Discussion

Dr. Conley G. Lacey, La Jolla, California. The authors retrospectively studied 50 patients with early squamous cell carcinoma of the cervix to determine the clinical feasibility of the FIGO cervical cancer classification system as it applies to stage IA_2 disease. All information was extracted from the patients' records. A measurement of the lesion diameter or breadth, a critical dimension of the FIGO system, was not included in the analysis.

Considerable useful information alerting us to the perils involved in the diagnosis and management of

early cervical cancer was obtained from this study. For example, the impracticality of the FIGO system is suggested by the fact that 33 of the 50 patients (66%) were excluded from FIGO substage IA_2 by virtue of positive cone margins. This is not as serious an indictment as it may sound, however, since as a practical matter, most patients with positive margins would be excluded from conservative treatment even with use of the SGO criteria, particularly if the margin was involved by invasive disease.

The remaining 17 patients in the study had negative cone margins and otherwise conformed to the author's criteria for FIGO stage IA_2. It is these 17 patients who should form the nucleus for this study and the analysis of these 17 patients must provide the evidence to refute the FIGO system. Six of these 17 patients had residual disease on the hysterectomy specimen, two with carcinoma in situ and four with microinvasive or invasive carcinoma. We do not know the outcome of these patients. It would also be helpful to know the exact millimeter-by-millimeter depth of invasion, the breadth of invasion, the presence of node or other metastases, the presence of other risk factors such as vascular space involvement, the recurrence rate, and the survival for this group of 17 patients. Whereas some of this information may be present in this study, it is not segregated from the 33 patients excluded on the basis of positive cone margins and therefore cannot be identified and used to refute the FIGO criteria for stage IA_2.

However, the authors do appropriately point out that the danger in use of FIGO stage IA_2 criteria for patient management is clearly documented in the literature, in which the reported incidence of pelvic lymph node metastases in patients with invasion between 3 and 5 mm is 8%. Dr. Greer, how many of the patients in this study had between 3 and 5 mm of invasion and what was the outcome of these patients?

This article is a modest impeachment of FIGO substage IA_2. It would be greatly strengthened by a careful pathologic review with inclusion of all FIGO criteria and other known risk factors. Results should be segregated according to those that do or do not conform to the study parameters. Thus, while I sympathize with the authors' opposition to FIGO substage IA_2, I cannot bring myself to join their indictment on the basis of the evidence presented in this paper.

I have one additional question. What were the characteristics of the four patients whose disease characteristics conformed to the FIGO criteria, who had negative cone margins but had residual invasive disease in the hysterectomy specimen?

Dr. Phillip Disaia, Irvine, California. I wish to defend the "Fathers of FIGO" at least in part. Until the new staging, we had a system that separated everything into microinvasion or stage IB. Stage IB encompassed everything from early stromal invasion to a 6 cm tumor. FIGO, in an attempt to define what Europeans term "microcarcinoma," studied the natural history of small cancers of the cervix. What is disappointing about this new staging system is that we do not have something to pass on to the practicing clinician. The FIGO staging system should not dictate therapy, and if we allow it to, we are misinformed. My recommendation is that clinicians apply the guidelines of the SGO, which were designed to help the clinican determine therapy. It has been the experience of most gynecologic oncologists that it is safe to apply the SGO guideline that simple hysterectomy is adequate for patients with <3 mm of invasion, with no vascular involvement, and no areas of confluence.

Dr. Greer, would you comment on that part of the SGO definition of microinvasion that has been controversial: confluence? Should it be included in the criteria? Finally, what is your recommendation to the practicing clinician about simple hysterectomy for patients with these lesions?

Dr. Frank R. Gamberdella, Santa Barbara, California. I was interested in the 17 cases with negative margins. I think you said four did not have negative results. You commented on the possible inadequacy of the carbon dioxide laser for conization. Should the clinician concerned about the possiblity of invasive lesion use a carbon dioxide laser cone or a traditional cold-knife cone for definitive diagnosis and better evaluation of the margins?

Dr. Greer (Closing). Dr. Disaia's question is the essence of this paper. As a gynecologic oncologist, I understand the implications of the FIGO classification. I have concerns about the interpretation of the FIGO classification in areas where tumor boards do not understand the implications of the definition of stage IA_2. They could recommend conservative management for a patient who needs radical surgery. As I pointed out in my conclusions, the experienced clinician will not fall into this trap. The SGO definition suitably fits the definition of microinvasion and the patient who fulfills these criteria can be conservatively managed. As presented in the text of the paper, no conclusions can be made regarding the risk factors of capillary-like space invasion, multifocal invasion, or confluence.

Twelve of the 17 patients with negative margins had invasions of ≤3 mm, and five patients had invasion of 3.1 to 5 mm. Residual invasive carcinoma at the time of radical operation was found in two patients in each measurement group. The four patients with residual invasive carcinoma are alive and free of disease after maximal treatment with radical operation. A patient with 1.8 mm of invasive carcinoma with capillary-like space invasion, confluence, multifocal invasion, and negative margins at the time of conization had recurrence at 61 months. She is alive with disease despite additional treatment.

Laser conization of the cervix with its coagulation artifact may obscure margins and depth of invasion. Any patient requiring a conization with a suggestion of invasion on the Papanicolaou smear, colposcopy, or biopsy should have cold-knife conization. This provides the most accurate information to make appropriate treatment decisions.

I have one additional comment. A recent article suggested that lesions invading between 3 and 5 mm could be adequately treated with a total abdominal hyster-

ectomy and a pelvic lymphadenectomy.[1] A 22.5% incidence of metastatic disease in parametrial lymph nodes in radical hysterectomy specimens has been recently reported.[2] Patients with stage IB invasive carcinoma of the cervix had an 11.4% incidence of positive parametrial nodes. These data are important to remember as we continue to evolve our guidelines for management of early invasive carcinoma of the cervix.

Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes

Miles J. Novy, MD,[a, b] Janice Haymond, MD,[a] and Mark Nichols, MD[a]
Portland and Beaverton, Oregon

Patients with a markedly effaced or dilated cervix and protruding membranes between 21 and 26 weeks' gestation were managed by Shirodkar cervical cerclage, perioperative tocolysis, broad-spectrum antibiotic therapy, and, in selected cases, inhibition of prostaglandin synthesis with indomethacin. The average duration of pregnancy after cerclage in nine patients was 11.8 weeks (range, 1 to 18 weeks). The mean birth weight was 2456 gm (range, 810 to 4341 gm). Eight of the nine pregnancies resulted in live infants (fetal survival rate, 89%); six patients (66%) were delivered at or near term. Preterm delivery occurred at 28 and 35 weeks' gestation in two patients and premature rupture of the membranes occurred in another at 25 weeks, 5 days after cerclage. There was no maternal postoperative or postpartum morbidity. A multifactorial approach to the patient with advanced cervical changes and protruding membranes in the second trimester resulted in a high rate of fetal survival and prolongation of pregnancy until term in the majority of patients. The Shirodkar cerclage holds a distensible cervix closed while the adjunctive medical therapy restores homeostasis. (AM J OBSTET GYNECOL 1990;162:1412-20.)

Key words: Shirodkar cerclage, indomethacin, tocolysis, antibiotics, preterm delivery

Most physicians manage cervical insufficiency with prophylactic cerclage placement with a modification of the technique described by Shirodkar[1] or McDonald.[2] Occasionally a woman is seen with a markedly effaced or dilated cervix, visible or protruding membranes, and a live intrauterine pregnancy. Results of cerclage placement in such unfavorable circumstances are acknowledged to be far less successful than when applied prophylactically. However, several authors have reported fetal salvage rates ranging from 47% to 91%.[2-5] It is commonly suggested that the McDonald cerclage (or modifications thereof) is the procedure of choice in the emergency situation, whereas some authors believe the Shirodkar procedure is technically not feasible for advanced cervical changes.[4, 6]

In this article we describe our experience with the Shirodkar cerclage in nine patients who were seen with a markedly effaced or dilated cervix and visible or protruding membranes. Management of these patients was augmented by preoperative and postoperative tocolysis, antibiotic therapy, and in selected cases, inhibition of prostaglandin synthesis.

Patients and methods

Nine consecutive patients from the authors' personal series in the 5-year period from 1984 to 1989 were treated by Shirodkar cerclage for advanced cervical effacement, dilatation, or both during the second trimester of pregnancy. Patients varied in age from 18 to 39 years. Six were multigravid and three were primigravid women. All patients were referred with the diagnosis of markedly effaced or dilated cervix with protruding or bulging membranes and presented between 21 and 26 weeks' gestation (mean gestational age at time of cerclage was 23.5 weeks). Three women presented with premature onset of contractions; five women presented with painless or silent cervical changes, and one presented with a displaced McDonald cerclage. The chief complaint that brought attention to the preterm cervical changes was a sensation of pelvic or vaginal pressure or a pink watery discharge in three patients. Symptomatic onset of uterine contractions was noted in three. Advanced cervical changes were detected in three patients on routine pelvic examination. Three patients had a positive history for diethylstilbestrol exposure in utero. Four of the nine patients had a history of second-trimester pregnancy loss or preterm delivery (Table I). Only one patient had a prior diagnosis of incompetent cervix; she had a previous McDonald cerclage placed at 14 weeks in the current pregnancy.

Selection criteria for inclusion in this series of patients were as follows: (1) cervical effacement greater than 60% and dilatation greater than 2 cm but less than 5 cm, (2) visible protrusion of intact fetal membranes beyond the internal cervical os or bulging at or beyond

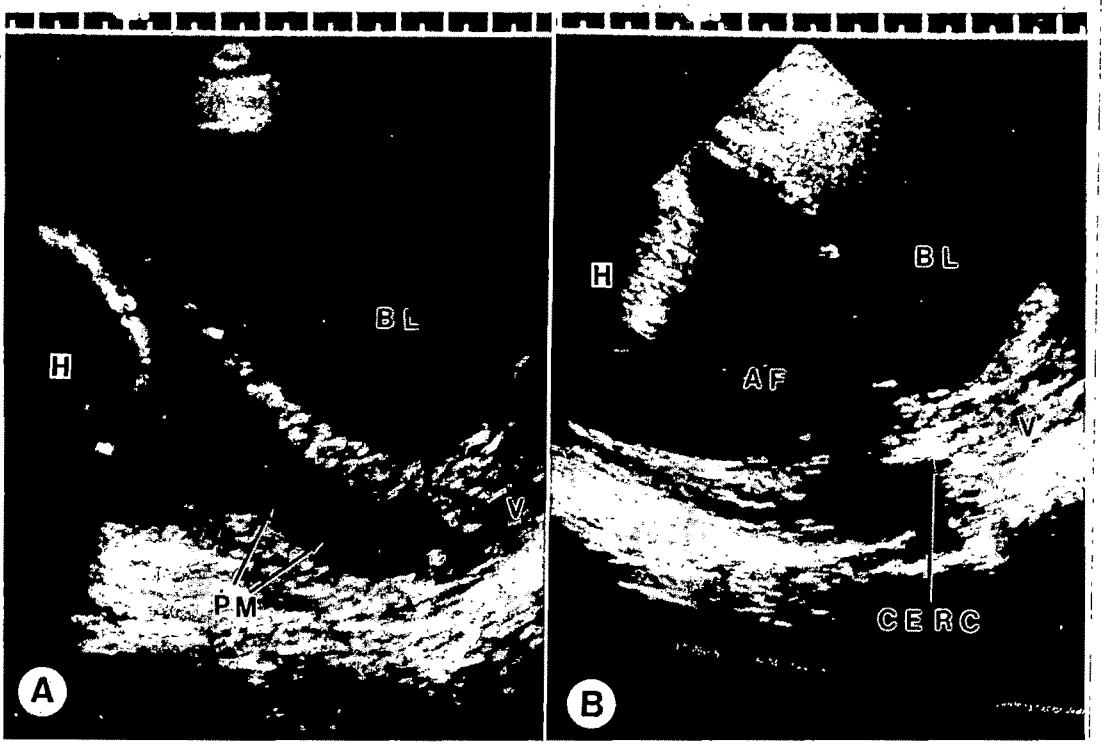

Fig. 1. Longitudinal scans of lower uterine segment and cervix (patient no. 4) by transabdominal ultrasonography before **(A)** and after **(B)** Shirodkar cerclage. *H,* fetal head; *AF,* amniotic fluid; *BL,* bladder; *PM,* prolapsed membrane; *CERC,* cerclage; *V,* vagina.

the external os, (3) a live intrauterine pregnancy of more than 20 weeks' and less than 27 weeks' gestation with no evidence of fetal anomalies, (4) absence of clinical evidence of chorioamnionitis, (5) absence of vaginal bleeding, and (6) favorable preoperative response to tocolysis.

The diagnosis of advanced cervical change and protrusion of the membranes was made by speculum or digital examination and confirmed by transabdominal ultrasonography (Fig. 1). The patient evaluation included cervical and urine cultures for aerobic and facultative bacteria. Cultures for genital mycoplasma organisms were obtained in several patients but were not routinely performed. Three patients had amniotic fluid cultures. All patients were admitted for observation and for continuous heart rate monitoring and uterine activity monitoring by external tocodynamometry. Patients were placed in moderate Trendelenburg position and, if the uterus was irritable, they received tocolysis by intravenous magnesium sulfate, ritodrine, or terbutaline, 0.25 mg, given subcutaneously according to standard procedures. Within 4 to 24 hours after admission and if uterine activity was absent or had substantially subsided, patients were taken to the operating room after informed consent had been obtained.

Surgical procedures. Deep general anesthesia was established with halothane or conduction anesthesia by subarachnoid block. Patients were placed in steep Trendelenburg position. The vulva was prepared in the usual manner, but the vagina was not cleansed by the nursing staff. After the open cervix was exposed with retractors, the vaginal walls and fornices were carefully prepared or irrigated with povidone-iodine solution under direct vision by the surgeon. Before operation, patients received 0.25 mg of terbutaline subcutaneously to further promote uterine relaxation and recession of protruding membranes. By means of sterile technique and ultrasonic guidance, amniotic fluid was removed (200 to 800 ml) in two cases by syringe to aid in decompression of the bulging membranes as previously described.[7]

The edges of the cervix were grasped gently by Babcock forceps or, if too thin and friable, the vaginal wall was grasped in the anterior and posterior fornices. The Shirodkar cerclage technique with modifications was used for the emergency cerclage (Fig. 2). The vaginal mucosa was incised transversely with long Metzenbaum scissors at the anterior and posterior cervical-vaginal junctions for a distance of 2 cm. Curved Allis forceps were used to grasp the anterior and posterior edges of the cut vaginal mucosa to compress the lateral paracervical tissue as previously described by Rust and Botte.[8] This maneuver facilitates passage of a 5 mm Mersilene tape (Ethicon RS-21, Ethicon, Inc., Somer-

ville, N.J.) with large needle and blunt tip. A finger was placed in the cervical canal to guide the needle and to avoid perforating the cervix or the membranes. In two patients (No. 5 and No. 9), a second cerclage tape was placed above the first tape for security and to create additional cervical length. The knot was tied anteriorly and a tail of tape was left to protrude from the mucosal incision to ease removal before vaginal delivery.

Intravenous antibiotics were administered in the operating room before the cerclage procedure. With the exception of two patients who received ampicillin and clindamycin and amoxicillin, respectively, the other patients received cefoxitin, 2 gm intravenously, and treatment was continued for 24 to 72 hours after operation. In addition, five patients received erythromycin, 1 gm orally daily, for a minimum of 10 days after operation. Patients received intravenous magnesium sulfate or ritodrine in standard doses or subcutaneous terbutaline, 0.25 mg, as necessary for postoperative tocolysis. In the latter part of the study, we added indomethacin (Indocin, Merck, Sharp & Dohme, West Point, Pa.) sustained-release capsules, 75 mg orally twice daily for 3 to 7 days, to the protocol. Patient No. 5 required long-term indomethacin therapy for a total of 23 days because of intermittent episodes of premature contractions. Patients were seen at weekly intervals for pelvic evaluation of cervical length and effacement supplemented by transabdominal ultrasonographic examinations at frequent intervals. Doppler echocardiography was used to monitor fetal ductus flow velocity

Tocolytic therapy	*Delivery*	*Neonate*
Magnesium sulfate, terbutaline	Repeat cesarean section	Male, 2581 gm, living and well

in three patients who received indomethacin. In the absence of progressive uterine contractions, patients were allowed to ambulate at will although vigorous physical activity was restricted. Intercourse was not contraindicated after a reasonable postoperative interval. Cerclage sutures were removed at 37 to 38 weeks' gestation, or whenever labor became established or after premature rupture of membranes (PROM).

Results

The results of emergency Shirodkar cerclage for the treatment of advanced cervical effacement, dilatation, and protruding fetal membranes are shown in Table I. The open cervix was closed without intraoperative complications or rupture of the membranes in all nine women. Two of the women had double sutures placed. Eight of the nine pregnancies continued and resulted in live births of infants (including one set of twins) who are living and well (fetal survival rate, 89%). Six patients (66%) were delivered at or near term by vaginal delivery or after repeat cesarean section. The average duration of pregnancy after cerclage placement was 11.8 weeks (range, 1 to 18 weeks). The average birth weight was 2456 gm (range, 810 to 4341 gm).

After elective cerclage removal spontaneous labor developed at or near term in four patients and repeat cesarean section was performed at term in two patients with the cerclage left in place. Preterm labor that did not respond to tocolysis occurred at 28 weeks' gestation in one patient (No. 3) and resulted in cerclage removal and vaginal delivery of a preterm infant that survived. Preterm premature rupture of the membranes occurred in one patient at 25 weeks' gestation (No. 7) 5 days after cerclage placement. *Bacteroides* species and gram-negative bacilli were isolated from the amniotic fluid in this patient. The cerclage was removed at the patient's request and an 810 gm infant was delivered that died 8 days post partum as a result of extreme prematurity and respiratory distress syndrome. Only three of the 10 infants were admitted to the neonatal intensive care unit. There were no operative or anesthetic complications, although prolonged Valsalva maneuver occurred before extubation in one patient who received a general anesthetic. Intraoperative blood loss was uniformly less than 125 ml. Partial displacement of the cerclage suture occurred in one patient at 36 weeks' gestation. Our patients did not experience clinical chorioamnionitis or postoperative or postpartum sepsis. Urine cultures were negative and cervical cultures grew normal vaginal flora except from patient No. 5 who had *Gardnerella vaginalis* infection. Amniotic fluid cultures were negative except in patient No. 7 as noted above. Microbiologic studies of the placentas and fetal membranes were not performed.

Comment

The patient with advanced cervical effacement and dilatation of the cervix and with membranes at the level of the external os or bulging into the vagina presents a formidable therapeutic challenge. At 27 to 28 weeks' gestation or thereafter, such patients are usually managed expectantly with bed rest and tocolysis and more recently with antibiotic therapy.[9] Survival rates exceed 90% in most neonatal intensive care units with infants with birth weights greater than 1000 gm. Despite this, short-term morbidity and the expense of neonatal intensive care are high, up to 33 weeks' gestation. The survival rate of infants weighing 500 to 999 gm is only 30% to 40% and of these survivors, one fourth are moderately to severely handicapped.[10] Therefore every reasonable effort should be made to prolong gestation safety for the previable or very-low-birth-weight fetus.

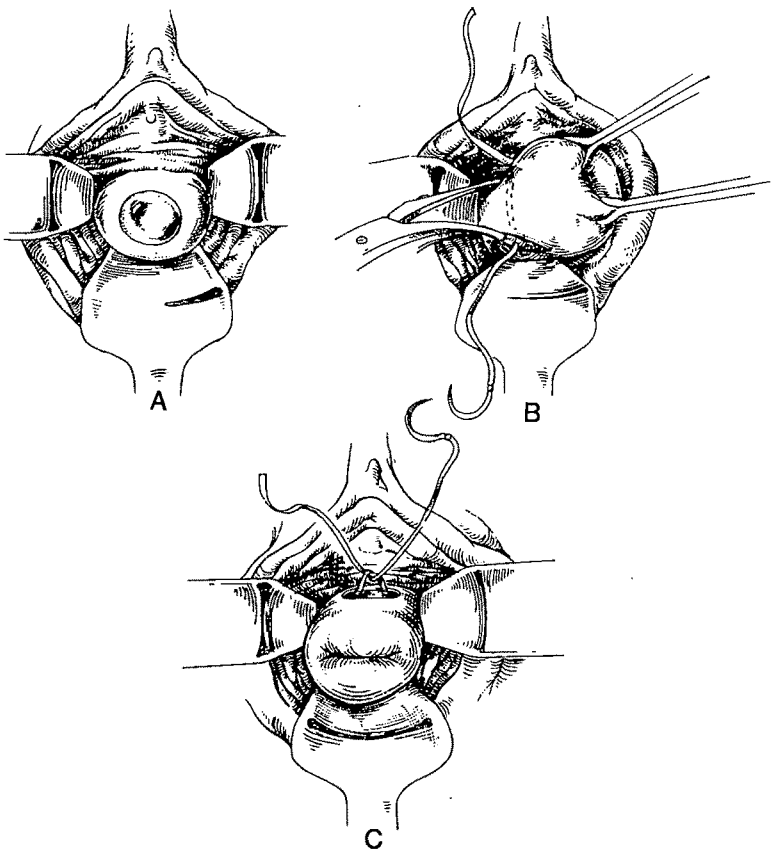

Fig. 2. Modified Shirodkar technique. **A,** Open cervix and protruding membranes are exposed with retractors. **B,** Cervical edges are grasped with Babcock forceps. Curved Allis forceps grasp edges of incised anterior and posterior vaginal mucosa and compress paracervical tissue, thereby facilitating passage of the needle with 5 mm Mersilene tape (Ethicon RS-21). **C,** After the membranes have been reduced, the cervix is closed by tying knot anteriorly.

The results of this uncontrolled series of patients suggest that emergency cerclage up to 26 weeks' gestation has an important role in promoting fetal survival. Our success rate in terms of infant survival was 89%, and six of nine patients were delivered at or near term without maternal complications. It is the experience of most obstetricians that unless the open and effaced cervix with bulging membranes is closed surgically in the second trimester, it is unlikely for such a patient to carry the pregnancy to viability and exceedingly rare to reach term.[4] Goodlin[5] reported that preterm delivery was inevitable and the fetal survival only 20% in patients treated expectantly for bulging membranes between 23 and 27 weeks' gestation. Similar results were reported by Varma et al.[11]

Although Shirodkar and McDonald techniques have been used by various authors with approximately equal frequency (Table II), there is a bias that the McDonald suture is technically easier, requires less operating time, produces less surgical trauma to the cervix, and is especially applicable to the emergency situation.[2, 6] Some authors have even stated that it is technically not advisable to close the cervix with a Shirodkar-type cerclage when the cervix is effaced.[4] Our experience is at odds with that view. We suggest the Shirodkar method has the following advantages for emergency as well as prophylactic cerclage: (1) stronger circumferential support because it is placed closer to the cervical and uterine-isthmic junction, (2) less chance of suture displacement or erosion through the cervix, and (3) protection of membranes from accidental puncture or trauma (abrasion) because of paracervical rather than intracervical placement of the suture.

The key elements to successful placement of a Shirodkar cerclage under emergency conditions are as follows: (1) uterine relaxation by preoperative and intraoperative administration of terbulatine, (2) decompression of bulging membranes by steep Trendelenburg position, ultrasonically guided amniocentesis if necessary, or other maneuver such as bladder distention,[12] (3) traction at the cervical-vaginal junction if the cervix is markedly effaced, and (4) use of a curved Allis forceps to compress the paracervical tissue at 3-o'clock and 9-o'clock positions to facilitate passage of the suture

*Advanced cervical effacement or dilatation with protruding or bulging membranes.

(Fig. 2, *B*). Although we have had equal success with general and conduction anesthesia, we prefer the latter to minimize the hazard of maternal straining during induction of anesthesia or during extubation.

The most frequently encountered complication of emergency cerclage in the presence of bulging membranes is rupture of the membranes during the perioperative period. Intraoperative rupture of the membranes was observed in 30% of the patients at Magee's Hospital[18] and in 17% of the patients reported by Olatunbosun and Dyck.[4] Goodlin[5] reported a combined 45% incidence of membrane rupture at operation or within 4 days after cerclage but his patients had unusually wide cervical dilatation (≥4 cm) and more than half had twins or triplets. We did not experience intraoperative rupture of the membranes in our nine patients but one patient who demonstrated positive amniotic fluid bacterial cultures did have rupture of the membranes 5 days after operation.

Uterine irritability and chorioamnionitis are other potential postoperative complications.[14] The majority of our patients demonstrated some degree of uterine irritability before cerclage (4 to 10 contractions per hour), although only three patients had symptomatic contractions. We have previously demonstrated a transient and modest increase in maternal plasma prostaglandin metabolites after cervical cerclage procedures.[15] Mean basal levels and the rise in prostaglandin metabolites were not related to cerclage type, trimester of pregnancy, or cervical status provided that dilatation was ≤3 cm, and effacement was ≤60%. Highest basal and postcerclage prostaglandin metabolite levels were associated with advanced cervical changes, uterine contractions, and membrane prolapse or rupture. Therefore we do not recommend routine administration of prostaglandin synthetase inhibitors for prophylactic cerclage procedures, even those performed in the second trimester. However, patients with advanced cervical changes in whom an emergency procedure is performed may benefit from use of antiprostaglandins.

It is likely that infectious complications after cerclage arise as a result of preexisting subclinical infection of the decidua or chorioamnion. This hypothesis is supported by the following data. (1) The recovery of microorganisms from the chorioamnion (in patients without cerclage) is strongly related to both histologic chorioamnionitis and to prematurity, yet most patients with histologic chorioamnionitis have no clinical signs of infection.[16] (2) Intrauterine infection increases prostaglandin production[17] and basal prostaglandin levels are increased in patients with advanced cervical changes and protruding membranes.[15] (3) The presence of cerclage at the time of premature rupture of the membranes does not increase maternal or neonatal infectious morbidity.[18]

Goodlin[5] maintained eight patients for 2 to 14 weeks after premature rupture of the membranes with cerclage in place without sepsis, although he did observe intrauterine growth retardation in several infants. There are increasing data to indicate that the risks associated with prematurity largely exceed the risks of infection.[18] In the absence of clinical chorioamnionitis, immediate removal of the cerclage after premature rupture of the membranes may not be advisable for the very premature fetus.

The strong association between infection within the uterus and prematurity suggests that microbial factors play an important role in a large percentage of previously unexplained preterm births. Cervical or vaginal microflora or the inflammatory reactions they produce release factors (e.g., proteases, collagenases, prostaglandins, and lymphokines) that initiate or predispose to uterine contractions, cervical ripening, and rupture of membranes.[17, 19] Microorganisms are recovered from the chorioamnion in the majority of women with preterm labor.[16] The recovery of bacteria within fetal membranes is fivefold higher than from amniotic fluid, suggesting that positive amniotic fluid cultures represent a later stage of ascending infection.[16, 20] Women in preterm labor with infected amniotic fluid tend to be delivered at earlier gestational ages despite tocolytic therapy than women with sterile fluid.[20] Although there are

occasional reports of successful treatment of intraamniotic infection with antibiotic therapy,[21] it is likely that detection of microorganisms in amniotic fluid will identify patients who are less suitable candidates for emergency cerclage because such patients have a higher incidence of failure and postoperative complications.[5, 14]

We treated our patients empirically with broad-spectrum intravenous antibiotics (e.g., cefoxitin) at operation and for several days after operation because subclinical infection of the chorioamnion (with anaerobic and facultative organisms) was likely. The use of erythromycin for 10 to 20 days is supported by recent evidence that antibiotics (including erythromycin and clindamycin) inhibit microbial proteases and that erythromycin (1 gm per day) given as an adjunct to tocolysis of preterm labor was associated with prolongation of pregnancy.[9] A historical comparison from the literature indicates a higher success with cerclage when adjunctive antibiotics were used (Table II). Multicenter studies are currently in progress to determine the role antimicrobial agents will play in the management of preterm labor.

We used the prostaglandin synthetase inhibitor indomethacin as part of our multifactorial approach in five patients because inflammatory disruption of decidual and membrane lysosomes increases local concentrations of arachidonic acid and thereby stimulates prostaglandin production.[22] Moreover, a variety of genital tract microorganisms produce phospholipases that augment the local release of prostaglandins.[19] Prostaglandins stimulate myometrial activity and promote collagen breakdown and cervical ripening, whereas indomethacin is known to arrest premature labor.[22] Short-term indomethacin treatment has little or no adverse effect on fetal well-being or neonatal outcome but prolonged indomethacin treatment is associated with oligohydramnios.[22, 23]

There were no apparent complications in our patients who received indomethacin 150 mg daily for periods of 3 to 7 days. In a recent study an increase in ductal velocity (suggesting constriction) was observed in 50% of indomethacin-treated fetuses between 27 and 31 weeks' gestation.[24] In all cases ductal constriction resolved within 24 hours after the cessation of indomethacin therapy. We performed fetal Doppler echocardiography and flow velocimetry during indomethacin therapy in three of our patients—two with singleton pregnancies at 23 and 24 weeks' gestation and the other with a twin pregnancy at 21 weeks' gestation. The results are shown in Table III. Only a small increase in ductal flow velocity was observed in the fetus of patient no. 5 after 23 days of indomethacin, and treatment was then discontinued. There appears to be a higher margin of safety with indomethacin use in the second trimester of pregnancy because the ductus of the very premature fetus is less sensitive to prostaglandin inhibition.[22, 24]

In summary, our initial results in nine patients indicate that an aggressive multifactorial approach to advanced cervical dilatation and effacement before 27 weeks' gestation (combining cervical cerclage, antibiotics, tocolytic therapy, and inhibition of prostaglandin synthesis) is associated with a high rate of fetal survival and with prolongation of pregnancy until term in the majority of patients. Retrospective control groups indicate that patients who have advanced cervical changes with protruding membranes during the second trimester have low fetal survival rates and a poor chance of reaching term. Moreover, patients who have cerclage placement are able to resume reduced physical activity, whereas similar patients treated without operative intervention generally require complete bed rest. Although our multifactorial approach is based on well-defined pathophysiologic mechanisms, the relative importance of the component parts needs to be evaluated in controlled and randomized prospective trials.

From a mechanistic standpoint, we view cerclage as a means to protect the fetal membranes from direct exposure to bacterial products (e.g., proteases) in the lower genital tract, to slow the rate of ascending infec-

tion, and, most importantly, to provide support against further prolapse and herniation of the membranes. A successful cerclage does not prevent the ripening process but it holds a distensible cervix closed while the adjunctive medical therapy is directed to remove the inciting stimuli and to restore homeostasis.

We thank Drs. Miles Seeley, Desmond Johnson, John Buckmaster, and Russell Dow for the opportunity to treat their patients. We acknowledge the expert assistance of Dr. Mary Jo Rice and Dr. Amy Thurmond in performing fetal echocardiography and cervical ultrasonography, respectively.

Discussion

Dr. Robert C. Goodlin, Denver, Colorado. In obstetrics, success is all that counts. If the diagnosis and procedures are all incorrect, but there is a good outcome, that is far better for the patient and the obstetrician than the reverse. Dr. Novy and colleagues have had a wonderful outcome for nine difficult cases, and have described some original concepts.

The modification and use of the Shirodkar technique in emergent situations is a major contribution. In the case with wide cervical dilation, I use both the Wurm and the McDonald cerclage. An intracervical inflated Foley bag keeps the membranes out of sight. Several of my colleagues use the Shirodkar technique. My sutures and knots are more likely to stay tight than theirs.

Dr. Novy speaks of ultrasonographic examination of the cervix. In the patient with a previable fetus and bulging membranes, I hope that a perineal ultrasonographic examination will be done of her cervix before rupturing the membranes or asking the patient to push. Often the membranes are in an hourglass pattern through a partially dilated cervix.

In my experience intraamniotic injection of high-dose antibiotics would have effectively treated Dr. Novy's case of chorioamnionitis and saved the pregnancy. Others consider this to too risky. Conversely, Dr. Novy places a cerclage in patients treated for premature labor with tocolytic agents, which seems a bit risky to me. The most risky procedure of all must be to place a cerclage in patients with a twin pregnancy after delivery of a nonviable twin. These risky procedures occur throughout the country, and I wonder what sort of informed consent Dr. Novy obtains for his technique.

Our colleagues are now demanding properly performed clinical trials, despite the fact that most of the progress in our field has come from case reports like Dr. Novy's. As an article of faith, I believe that a cerclage before the twenty-sixth week should be considered whenever there is significant cervical dilatation in the absence of painful contractions. However, our house

officers recently declined my advice and put to bed in our hospital a woman at 24 weeks' gestation with a cervix dilated 3 to 4 cm and with bulging membranes; she remained at bed rest for 10 weeks. Labor was induced at 37 weeks because of a fetus with intrauterine growth retardation. The costs of a randomized trial of bed rest versus cerclage, if done properly, would be tremendous. If our colleagues demand this before using the technique in advanced cases of cervical dilatation with previable fetuses, their patients will suffer preventable losses. Although Dr. Novy speaks of a clinical trial, I wonder if he would be willing to participate, given his own success?

One of the correlations I have noted with patients with advance cervical changes, is a subsequent fetus with intrauterine growth retardation. This is apparently true in Dr. Novy's experience and probably represents the spectrum of premature labor. My final question, Dr. Novy, is when does a case of incompetent cervix become premature labor?

Dr. Raphael B. Durfee, San Diego, California. Dr. Novy continued where many of us left off. To those, like me, who were pioneers in the use of cerclage it is very complimentary to have him adapt this old procedure to modern situations. I did the third and fourth cerclages in the United States, in the Army Hospital in Fort Leavenworth, Kansas. I used kangaroo gut that came in a test tube and the operation was successful. Dr. Novy also helped to further a procedure that Dr. Ralph Benson and I introduced called abdominal cerclage. One problem that we have always had is the management of prolapsed membranes. Dr. Louis Gluck, a perinatologist with us at University of California, San Diego for many years, was of the opinion that all these women had some degree of infection of the amnion. He thought that cervical incompetence was not an anatomic failure necessarily, but often a functional one related to various aspects of infection. Dr. Novy has made an incredibly important contribution to the use of this procedure by using differrent antibiotics to manage potential, if not actual, infection. His sucess rate reflects this. Dr. Novy, how do you avoid tying part of the prolapsed membranes into the cervical canal tissue when you tie down the cerclage tape? If you produced enough pressure to cause necrosis, you would defeat your purpose.

Dr. Russell K. Laros, San Francisco, California. One trick we have used to deal with the problem of avoiding the membranes has been to use a Foley catheter with a 60 ml balloon. The catheter tip is cut off and the balloon is filled with water. The balloon is used to push the membranes inside as you tie down the cerclage and then the balloon is deflated. The method has been very helpful and eliminates the problem of catching the membranes in the suture.

Dr. Novy (Closing). I have been concerned about the use of the Wurm and McDonald sutures for emergency cerclage because they do not hold well in a markedly effaced and thinned cervix. There is an increased hazard of perforating the membranes each time the needle is passed through the substance of the cervix. It has always seemed more rational to use an encircling band of the Shirodkar type to take advantage of the paracervical tissue as much as possible. Naturally, successful application of the cerclage requires at least partial reduction of the herniated membranes. Transabdominal aspiration of amniotic fluid will not be successful in helping to reduce the membranes unless the uterus is sufficiently relaxed. On several occasions, I have applied a second cerclage higher up while exerting traction on the first suture. A curved Allis forceps is useful to compress the paracervical tissue and displace the membrane so that the risk of puncture is minimized.

We do obtain informed consent from our patients and emphasize the risks of intraoperative and postoperative rupture of membranes. We have been happy with our low or absent maternal morbidity. If we include patients who have positive amniotic fluid cultures, we may expect to see more complications. We are designing a prospective trial at our institution and, in my opinion, part of the protocol should include identification of infections in the amniotic fluid. This represents a later stage of ascending infection, which is associated with a higher incidence of complications such as premature rupture of the membranes and chorioamnionitis. Intrauterine growth retardation may be associated with various conditions for which cerclage is performed, such as bicornuate or unicornuate uterus, but it is not a complication of cerclage per se provided there is normal amniotic fluid volume.

When does an incompetent cervix become premature labor? Dr. Durfee suggested an answer in his comment. In a substantial percentage of patients preterm labor will present painlessly as a functionally "incompetent cervix" but uterine irritability will be detected by careful monitoring. Prostaglandin release by microorganisms or inflammatory cell products leads to the triad of cervical softening, uterine contractions, and weakening or rupture of the membranes. Depending on host factors, any one part of this triad may be prominent clinically in one patient and not in another. This would explain why primigravid patients who lack an anatomically defective cervix develop "painless cervical dilatation" and why the incompetent cervical os syndrome is not always repetitive. For these reasons, we should include functional causes in our differential diagnosis of preterm labor and cervical incompetence. This, in turn, leads logically to an integrated, multifactorial approach to therapy.

What is fetal distress?

J. T. Parer, MD, PhD, and E. G. Livingston, MD
San Francisco, California

Fetal distress is a widely used but poorly defined term. This confusion of definition compounds the difficulty of making an accurate diagnosis and initiating appropriate treatment. The fetus reacts at the onset of asphyxia with a remarkable series of responses, primarily a complexly regulated redistribution of blood flow that serves to limit the deleterious effects of oxygen limitation in vital organs. This enables the fetus to survive asphyxia intact unless the insult is profound or prolonged. The most common asphyxial stresses imposed on the fetus during labor are insufficiency of uterine blood flow, or insufficiency of umbilical blood flow, and occasionally decrease in uterine arterial oxygenation. Each of these stresses produces characteristic fetal heart rate patterns: late decelerations, variable decelerations, or prolonged bradycardia. There is strong evidence that the presence of normal fetal heart rate variability represents normal central nervous system integrity, including adequate oxygenation. A decrease or loss of variability in the presence of these patterns is a sign that the physiologic compensations are overwhelmed as a result of the severity of asphyxia. Knowledge of the fetal responses to asphyxia, together with the known evolution of fetal heart rate patterns during asphyxia, should allow a more accurate definition of the onset of unacceptable asphyxia, and more rational management and timing of intervention. (AM J OBSTET GYNECOL 1990;162: 1421-7.)

Key words: Asphyxia, fetal distress, fetal heart rate monitoring, fetal physiology

The term *fetal distress* is widely used as an indication for cesarean section, or as justification for midforceps delivery. It is often prefaced by the term *acute* or *chronic*. Some authors have defined it as "late decelerations," "severe variable decelerations," or "tachycardia with total loss of short-term variability" of the fetal heart rate.[1, 2] Others believe that fetal acidosis is necessary to define fetal distress, or they imply that a depressed Apgar score is required.[3]

Most physicians recognize that fetal distress is related to asphyxia, with the implication that it should be avoided. We, and others,[4] believe that fetal distress is a poorly defined term, and that this diffuseness of understanding is a disservice to obstetrics. We believe that the term can be more accurately defined with our current understanding of fetal cardiorespiratory responses during labor, and that a better understanding of the pathophysiology of asphyxia will result in improved management of the fetus during labor.

Asphyxia and fetal morbidity

Asphyxia has the pathologic meaning of insufficiency or absence of exchange of the respiratory gases, although etymologically it is derived from the Greek word meaning pulseless. Its severity is described in terms of acidosis, hypoxemia, and hypercarbia. With prolonged hypoxia, anaerobic metabolism within the organism results in lactic acidemia, which aggravates the acidosis.

In a strict sense all fetuses are born "asphyxiated" because there is a mixed respiratory and metabolic acidosis and hypoxemia in newborns with a totally normal intrapartum course and outcome. In a series of 899 fetuses, at birth the mean umbilical arterial pH was 7.2 (SD ± 0.08) and base excess −8.3 mmol/L (SD ± 4.0).[3] The carbon dioxide tension calculated from these means is 49 mm Hg. This "asphyxia" is mild in nature and is not considered a pathologic condition. Such blood gas levels at birth may even be physiologic, to ensure the rapid assumption of the adult circulation and respiration. It is noteworthy that the range of normality calculated as mean − 1 SD is extreme, including a pH as low as 7.12, and base excess to −12 mmol/L.

Severe fetal asphyxia can cause cerebral palsy and lesser degrees of neurologic damage, although it is now clear that the proportion of cerebral palsy caused by birth asphyxia is relatively small, perhaps less than 10%.[5, 6] The degree of damage to any individual fetus after severe asphyxia can be quite variable. For example, some fetuses may not survive the episode in utero, others have central damage that results in a surviving newborn with neurologic defects, and still others survive without apparent deficits.[7-9]

At one end of the scale, we have reasonably good evidence for the limits of fetal tolerance for complete

absence of oxygen delivery. Myers[10] showed that after complete cessation of fetal oxygen delivery, hypoxemia and both respiratory and metabolic acidosis occurred rapidly. Intact survival generally did not occur after 10 minutes of oxygen deprivation. Survivors generally had brain stem lesions, although the patterns of damage were variable. If oxygen delivery was prevented for 25 minutes, fetuses could be resuscitated but apparently the hypoxic damage to numerous organs including the heart was so severe that death occurred within a short time. Myers et al.[10-12] have also studied prolonged partial asphyxia in sheep and monkeys as a result of a variety of mechanisms. As with brief complete asphyxia, they found a variable pattern of response. Survivors generally had neurologic deficts as a result of cortical lesions, in contrast to those subjected to complete oxygen cessation. Prolonged partial asphyxia in the above studies has been difficult to define, probably because of the several components, such as degree of hypoxemia, duration, and initial condition of the fetus.

Although several other workers have attempted to relate fetal asphyxia to electrophysiologic or histologic effects on the brain,[13-16] the majority of studies of fetal asphyxia have concerned fetal physiologic responses, including cerebral oxygen uptake to brief periods of asphyxia without benefits of electrophysiologic, pathologic, or behavioral follow-up.[17-22] We believe that ideally it is better to quantitate severity of asphyxia by such measures as adequacy of cerebral or myocardial oxygenation. Currently there is no linkage of the pathophysiologic quantification of asphyxia with electrophysiologic consequences that signify unacceptable damage.

The production of cerebral damage under controlled physiologic conditions has proved to be difficult. It is known that asphyxia sufficient to result in a preductal arterial oxygen content below 1 mmol/L usually is associated with reduced cerebral blood flow and oxygen uptake.[23] However, such asphyxia does not necessarily result in irreversible electrocorticographic changes, or cause neuronal necrosis.[24] The fetus is apparently able to temporarily lower its cerebral metabolism by various compensatory mechanisms.[25] There are strong suggestions from the literature regarding newborns that hypotension is necessary for cerebral damage, but this is not unequivocally demonstrated for the fetus. It seems evident, however, that minor or brief periods of asphyxia per se do not cause cerebral damage. The insult must be profound and prolonged,[7-9] but the quantitative details have not yet been established.

If all infants are born with at least "physiologic" asphyxia, and in the extreme case severe asphyxia causes brain damage, how then can we recognize the transition zone? It is clearly important to recognize the transition because if obstetric intervention occurs too early, it may be inappropriate, or if too late, the fetus may be damaged. A tentative definition of fetal distress follows: persistent fetal asphyxia that, if not corrected or circumvented, will result in permanent neurologic damage or death.

This is not a particularly valuable working definition unless clinical markers of impending or actual fetal neurologic damage can be defined.

Fetal responses to asphyxia

There have been many recent studies of fetal responses to oxygen limitation provoked by various means, including reduced uterine and umbilical blood flows.[26] It is now well established that a number of important cardiorespiratory adjustments occur during hypoxia or asphyxia to preserve the oxygenation of certain "priority" organs. Initially there is a selective vasoconstriction of certain organs and vasodilatation of others, which results in an increased blood flow to the brain, heart, and adrenal gland, retention of blood flow to the placenta, and decreases in blood flow to the other organs or areas of the body.[27, 28] The overall cardiac output remains fairly stable at moderate degrees of hypoxia, but at more severe degrees of hypoxia or asphyxia cardiac output decreases.[29, 30]

A further compensatory response is that overall fetal oxygen consumption declines to values as low as 50% of control.[31] This level can be maintained for periods of up to 45 minutes and is completely reversible on cessation of hypoxia. It is thought that this represents a decrease in oxygen consumption in those vascular beds where circulation is inadequate. There is gradual development of a metabolic acidosis, primarily as a result of the accumulation of lactate.[32] This probably represents anaerobic glycolysis in those vascular beds where oxygen supply is limited.

Numerous mechanisms responsible for these hemodynamic alterations have been identified. These include oxygen levels,[17, 33] carbon dioxide tension,[34] α-adrenergic activity,[35] β-adrenergic activity,[36] arginine vasopressin,[37] endogenous opioids,[38] and prostaglandins.[39] There are undoubtedly other as yet unidentified mechanisms.

When asphyxia becomes severe, these protective mechanisms are overwhelmed, and there is intense vasoconstriction of all vascular beds.[29] At such degrees of hypoxia, blood flow to and, therefore, oxygen consumption of all organs, including those previously favored, most likely decreases. Cerebral and myocardial oxygen consumption can be maintained during moderate hypoxia by the increase in blood flow to the respective organ that exactly balances a decrease in arteriovenous oxygen content difference.[17, 40] However, at more severe degrees of asphyxia, when an adequate compensatory increase in blood flow to the organs no

longer occurs, the oxygen consumption can no longer be maintained.[22, 23] This represents a point of decompensation of the physiologic mechanisms that had previously lessened the impact of relatively short periods of asphyxia on fetal vital organs. This stage most likely precedes the final bradycardia, hypotension, and death by a relatively short time. It is thought that hypoxic organ damage occurs during this phase. However, such observations do not assist in recognition of the degree of oxygen consumption deficit that can be tolerated before permanent damage occurs. This will require a combination of metabolic, electrophysiologic and pathologic studies.

Prognostic capacity of FHR variability

It was commonly stated in the past that fetal heart rate monitoring is extremely accurate in diagnosing fetal vigor when the pattern is normal, but that it is poor for determining depression when the pattern is "abnormal."[41, 42] That is, its specificity, or ability to correctly diagnose normal, was thought to be poor. This resulted in the overdiagnosis of "fetal distress," and at times unnecessary intervention leading to either cesarean section or potentially traumatic operative vaginal deliveries. We believe that this may be true if fetal heart rate (FHR) patterns are interpreted according to older concepts that considered the prominent "abnormality" to be decelerations of FHR with contractions.

Empirical clinical evidence strongly suggests that the addition of the determination of FHR variability to the FHR pattern interpretation can aid in improving specificity. Evidence for this view has taken the form of clinical observations[43] or retrospective surveys of outcome after monitoring.[44-46] The common trend in these studies is that the presence of FHR variability is almost invariably associated with fetal vigor at birth, even in the presence of various decelerations or bradycardias. A further observation is that of infants who died in utero while being monitored, none had the presence of normal FHR variability.[47] The corollary of this observation is that if the FHR has normal variability, the fetus is at low risk for immediate death caused by asphyxia.

The preceding observations and widespread clinical experience have resulted in the acceptance of FHR variability by many clinicians as a prime indicator of fetal vigor.[47] The acceptance of the efficacy of this approach to FHR interpretation is not, however, universal,[48-50] and we believe that the overdiagnosis of the "asphyxiated" fetus will continue until a physiologic basis for FHR variability is demonstrated, leading to more rational interpretation. The original interpretation of FHR patterns stressed the decelerations (late or variable decelerations) occurring with contractions, and equated their presence to "fetal distress," which then dictated operative intervention.[51] The alternative interpretation states that the decelerations, or bradycardias, indicate intermittent asphyxial "stresses" (generally insufficiency of uterine or umbilical blood flow), whereas the collective influence of these stresses on the fetal physiologic compensatory mechanisms is determined by the decrease or loss of FHR variability, signifying a cumulative oxygen debt and decompensation.[47] Thus the presence of FHR variability indicates central (nervous system, myocardial, or both) normoxia, whereas its decrease in the presence of the stress patterns indicates a decrease in the oxygenation of these organs.

It has long been recognized that FHR variability can be affected by numerous influences other than asphyxia. Such influences include congenital anomalies and drugs, and in some cases there is no apparent cause, although the infant is normal at birth. Examples of some factors responsible for decreased or absent variability include anencephaly, complete heart block, narcotic administration (presumably acting on the central nervous system), and atropine administration (presumably blocking oscillatory influences transmitted by the vagus nerve).[26]

The source of FHR variability is clearly complex, with inputs from many cycling physiologic phenomena, including respiratory arrhythmia, blood pressure fluctuations, and thermoregulation, at least in the adult.[52] However, many of the observations are most consistent with the theory that the presence of normal variability requires integrity of (1) the cerebral cortex, (2) the midbrain, (3) the vagus nerve, and (4) the cardiac conduction system.[47]

It is known that different fetuses have an intrinsic "quantity" of variability, and also that this can change with differences in fetal state.[53-55] It is also known that the components used to describe fetal state can be altered by hypoxia or hypercapnia[56] and by short periods of decreased uterine blood flow.[57, 58] Again, the presence of certain state variables can affect others; for example, during fetal breathing movements there is a respiratory arrhythmia,[59] and during prelabor myometrial activity there is a change to the quiescent state in fetal sheep.[60] It is important to be aware of such activities to make the appropriate distinction between asphyxial and nonasphyxial causes of decreased variability.

Clinical implications

There are basically three common means by which the human fetus can become asphyxiated (or hypoxic): (1) insufficiency of uterine blood flow,[29] (2) insufficiency of umbilical blood flow,[61, 62] or (3) a decrease in maternal arterial oxygen content.[31] Other mechanisms, for example, fetal anemia or increased fetal oxygen needs (in pyrexia), are relatively rarely seen clinically.

In clinical obstetrics these three common mechanisms can be recognized during labor (that is, in the presence of uterine contractions) by various FHR patterns. Uterine contractions are thought to cause the transient decelerations because of the concomitant decrease in uterine blood flow with the contraction,[51,63] or an associated decrease in umbilical blood flow (e.g., as a result of umbilical cord compression[51]). The patterns corresponding to the above mechanisms are late decelerations, variable decelerations, and persistent fetal bradycardia.[47] A prolonged stepwise insufficiency of uterine or umbilical blood flow would likewise be recognized as a bradycardia. It has been proposed that a fetus with normal FHR variability will not revert to one with absent FHR variability caused by asphyxia during labor unless one of these asphyxial "stress" patterns is present.[47] Conversely, if the FHR variability is absent on initial application of the FHR monitor, then it is not possible to distinguish between asphyxial and nonasphyxial causes of decreased FHR variability, and the fetal stimulation test or fetal blood sampling for determination of acid-base status must be performed.

On the basis of the above considerations, a tentative definition of fetal distress is as follows: progressive fetal asphyxia that, if not corrected or circumvented, will result in decompensation of the physiologic responses (primarily redistribution of blood flow to preserve oxygenation of vital organs) and cause permanent central nervous system and other damage or death.

The clinical means by which we currently use the above definition to ensure adequate fetal compensation is by noting the progress of severity of the FHR stress patterns, and the retention of FHR variability. Intermittent or sustained decreases in FHR variability in the presence of stress patterns are assumed to signal the onset of decompensation, unless asphyxia is ruled out by ancillary testing. There may be a role for fetal blood sampling, but in the presence of normal FHR variability its role is quite limited.[64,65] It is hoped that future physiologic studies, and correlation with FHR patterns, will further refine the definition of "fetal distress" and make the diagnosis more accurate in the clinical setting.

Discussion

Dr. Edward J. Quilligan, Irvine, California. In this article Drs. Parer and Livingston have attempted to define fetal distress by reviewing the fetal physiologic adaptations that occur with decreased oxygenation and serve to protect the brain, heart, and adrenals. The definition that they have developed is a logical one: progressive fetal asphyxia that, if not corrected or circumvented, will result in decompensation of the physiologic responses (primarily a redistribution of blood flow to preserve oxygenization of vital organs) and cause permanent damage to the central nervous system and other damage or death. The difficulty lies in the use of this definition clinically. We know the heart rate change is associated with a change in fetal oxygen (i.e., late, variable, or prolonged decelerations), so we can determine the first half of the definition with continuous heart rate monitoring. The authors would also like us to believe that the second half of the definition, decompensation, can be determined by examining the

heart rate variability. Although changes in heart rate variability have been shown to result from hypoxia, I am unaware of studies relating variability to decompensation.

Let us assume for a moment that they *do* reflect decompensation. Will it help clinically? Our goal is to prevent fetal death and damage without unnecessary cost to the mother. I would emphasize the latter *without unnecessary cost to the mother* because five of the seven randomized trials have demonstrated an increase in the cesarean section rate in the continuously monitored group.[1] In terms of reduction of intrapartum death, I believe continuous monitoring has accomplished that, even though the trials mentioned above do not prove it.[1] Nonrandomized trials such as the one by Dr. Yeh et al.[2] at University of Southern California do show a difference and reveal the large number of patients necessary to demonstrate this difference (about 100,000). I would agree with the authors that combining abnormal fetal heart rate pattern and fetal heart rate variability may reduce this unnecessary cesarean section rate for fetal distress, and still prevent antepartum deaths. It is in the prevention of central nervous system damage that we have difficulty. There is no good evidence in the literature that the frequency of central nervous system damage in infants is decreasing.[3] In fact, the opposite seems true. Furthermore, as the authors point out, a very small percentage of central nervous system damage is incurred during labor. When we studied infants who had cerebral palsy, there was an increased incidence of abnormal fetal heart rate patterns and absent variability, and there were fetuses in whom cerebral palsy developed without any typical fetal distress patterns.[4]

It appears to me that if we are to reduce central nervous system damage, we need additional information, such as what degree of lack of oxygen for how long causes brain damage? Although we have some information from Myers'[5] classic studies, it must be remembered that the study animals were anesthetized or heavily sedated, which may influence the brain's ability to tolerate hypoxia. To further confuse the issue, Clapp et al.[6] have shown that brain damage in fetal sheep can be caused by intermittent cord compression without fetal acidosis.

The authors have indicated the final event in fetal decompensation is the reduction in fetal brain blood flow as a result of a decrease in fetal cardiac output. It would be important to know whether the authors think if it is at this point that brain damage occurs. If so, do they see any role for the measurement of blood flow in the umbilical or carotid vessels to assist in determining this point of decompensation?

I do not mean to denegrate the role of continuous fetal heart rate monitoring in the management of labor nor the authors' explanation for the development of brain damage. I simply believe that there are a number of "blanks" in the equation at this time, before we can say we have the factual information to significantly reduce that small portion of brain damage that may occur during labor. These authors have done excellent work in helping to fill in those blanks, and I would urge them to continue their work.

DR. ROBERT GOODLIN, Denver, Colorado. The term *heart rate variability* is one that is dear to me. I think I introduced it at this society's 1970 meeting in Hawaii and Dr. Quilligan was my official discussant.[1] Like many things that I have done, it seems to have gotten out of hand. On our labor deck, for instance, we often cannot begin oxytocin administration or do certain other procedures because somebody has decided that the fetal heart rate tracing shows decreased variability. Zalar and Quilligan[2] showed that the loss of beat-to-beat variability had no significance. I suggest that there are many papers that show that loss of beat-to-beat variability by itself is a rather useless concept.[3] I hope that the authors' article will not now carve the concept in stone so that we cannot dig ourselves out of the hole. It seems to me that if you call it *asphyxia,* you must obtain a fetal blood sample, scalp or otherwise.

DR. PARER (Closing). Dr. Quilligan, you ask if I have solid evidence that loss of FHR variability in an appropriate setting does signify decompensation. I do not have incontrovertible, hard data yet. I think I have provided most of the physiologic data I have and little

of it is published. We have not closed the circle yet, but I accept as an article of faith that these data will become available. The reason I accept this is the wide clinical experience I had at Los Angeles County Hospital under the guidance of yourself and Dr. Hon. Since that time I have looked for exceptions to the rule "fetuses born with normal heart rate variability will have an Apgar score above 7 at 5 minutes no matter what else is going on with the heart rate." There are very few exceptions to that rule, maybe one in a thousand. When there is heart rate variability, the infants are vigorous at birth. There are more formal data available. Krebs et al., for example, conducted a study and reached similar conclusions (see reference 45). Variability was determined within approximately 30 minutes of birth and the predictability for a vigorous fetus was 98%. This is very good and holds true in the presence of late and variable deceleration.

Your second question, why the incidence of cerebral palsy has not decreased over the years despite our intensive monitoring, is a difficult one. One problem is that intrapartum asphyxia is probably responsible for <10% of all cerebral palsy. No matter how well we abolish intrapartum asphyxia as a cause of cerebral palsy, we will not alter the overall incidence much. My view on this is that intrapartum asphyxia is a potentially avoidable cause of cerebral palsy; that is why I think we should concentrate our efforts to avoid this problem.

As we mentioned in discussion of a previous paper, part of the problem with some controlled trials of fetal monitoring is that the rules for heart rate interpretation were quite different from those accepted today. Two aspects deserve mention. First, there was no emphasis on heart rate variability, and second, response times were not clearly defined. One trial required that the response time be less than 90 minutes in the case of an infant with signs of asphyxia. Now, if we say that an infant can sustain brain damage within 10 minutes, then 90 minutes is totally inappropriate. That is not the fault of electronic fetal monitoring but rather the fault of the obstetric facility that cannot intervene more quickly.

Dr. Quilligan, you mentioned a subject I want to emphasize: the degree and duration of asphyxia. There is almost certainly an interaction between duration and degree of asphyxia on the one hand and the previous condition of the fetus (whether or not it has glycogen stores or is growth retarded) on the other. The answer to these questions will quite clearly affect the relationship between asphyxia and brain damage.

Dr. Kirschbaum, you would like to call fetal distress *asphyxia* and we are not far apart on that. You also want to bring dysfunction of other organ systems into the definition and I would be delighted to do that. I agree that other organ dysfunction should ultimately be part of the overall definition of intolerable asphyxia. The difficulty is that in a clinical setting, it is difficult enough to include only the brain.

Dr. Goodlin, you pointed out that I did not emphasize sufficiently the fact that we cannot isolate loss of FHR variability. Loss of FHR variability signifies decompensation of physiologic mechanisms only in a particular setting. For simplicity, I will say that if a fetus has a loss of variability during labor in the absence of deceleration or bradycardia, you can be almost 100% sure it is not a result of asphyxia. The setting must be appropriate before you can rationally call a loss of variability the result of asphyxia.

You made another point about fetal blood sampling. If you study some of the original papers of fetal blood sampling, you will find that they have a nagging inaccuracy of 10% or 20%; that is, if you do 100 fetal blood samples on normal fetuses during labor, acidosis will be found in about 10 or 20. Thus, if you have obtained a fetal blood sample for whatever reason and proceed to act on the result, these infants at birth would be quite vigorous. The inaccuracy inherent in the interpretation of fetal blood samples far surpasses the inaccuracy in determining FHR variability. The reason is that peripheral blood, which can rapidly turn cyanotic on vasoconstriction, is being sampled. What we need is a central marker of fetal integrity. I believe that FHR variability is the best candidate for that.

A comparison of the morbidity of midforceps and cesarean delivery

Richard A. Bashore, MD, William H. Phillips, Jr., MD, and Charles R. Brinkman III, MD
Los Angeles, California

Neonatal and maternal outcome in 358 midforceps and 486 cesarean deliveries was compared by retrospective analysis. Neonatal outcome was evaluated on the basis of Apgar score, cord blood gas values, admission to the neonatal intensive care unit, and birth trauma. Maternal outcome was based on intraoperative and postoperative complications, blood loss, and hospital stay. There was no increase in significant short-term neonatal morbidity in the midforceps group, while maternal morbidity was higher in the cesarean delivery group. It is concluded that, in selected cases, midforceps delivery is safe for the neonate and mother. (Am J Obstet Gynecol 1990;162:1428-35.)

Key words: Midforceps, outcome

Considerable controversy exists as to the place of midpelvic forceps deliveries in present-day obstetric practice. Reports that indicate increased neonatal morbidity with the use of midforceps[1-4] and the availability and safety of cesarean deliveries are cited as ample reasons for abandoning the midforceps procedure.

Other reports,[5,6] however, have noted no increase in neonatal risk with midforceps delivery and also point to the increase in maternal morbidity and mortality with cesarean delivery. The reported differences are difficult to reconcile because of the multiple variables involved. The station at which the midforceps procedure was performed, gestational age, preexisting medical and obstetric problems, and the experience and skill of the operator are but a few of the factors that influence neonatal and maternal outcome. In addition, midforceps have been compared to other methods of delivery that were not appropriate alternatives.

To provide additional information as to the risk of midforceps procedures, a comparison of neonatal and maternal outcome associated with midforceps and cesarean delivery in the second stage of labor was carried out. The deliveries occurred over an 8-year period in an institution where midforceps was used regularly in the management of dystocia or fetal distress.

Material and methods

Between Jan. 1, 1981, and Dec. 31, 1988, there were 18,469 live births at the University of California, Los Angeles, Medical Center. Of this total, 358 midforceps and 486 cesarean deliveries, which were performed during the second stage of labor for management of dystocia or fetal distress, were retrospectively analyzed for a comparative study of neonatal and maternal morbidity.

All deliveries were of a single, term fetus in a vertex presentation with a gestational age of ≥37 weeks. Specifically excluded from the study were patients with medical and obstetric problems that could affect outcome regardless of the method of delivery. These conditions included severe preeclampsia and chronic hypertension, diabetes mellitus more advanced than class B, placenta previa, and abruptio placentae. Also excluded were cases of failed midforceps and vacuum extractions.

The definition of midforceps applicable to this study was that in use before the appearance of the revised definition proposed in the American College of Obstetricians and Gynecologist Committee Opinion published in 1988. However, only those midforceps procedures involving rotation of the fetal head from an occipitotransverse or oblique occipitoposterior position at station +1, +2, or +3 (centimeters below the ischial spines) were included. Most of the oblique occipitoposterior positions were rotated to direct occipitoposterior and the infants were delivered as such. Only two midforceps deliveries were performed at a +1 station; the remainder were at +2 or +3 station. The majority of vaginal operative deliveries were performed with Kielland forceps. Only cesarean deliveries performed

with the fetal head at similar stations were included. The position of the fetal head before delivery was not tabulated for cesarean or midforceps operations performed for management of fetal distress.

The term *dystocia* was used with reference to patients with an arrest of descent and prolongation of the second stage of labor beyond 2 hours. The labor pattern before the onset of dystocia was not evaluated. All patients had continuous electronic fetal monitoring during labor. Fetal distress was diagnosed by the physician in attendance on the basis of an abnormal fetal heart rate pattern including persistent late decelerations, severe variable decelerations, or sustained bradycardia. Fetal scalp blood samples were obtained when indicated. No attempt was made to tabulate the type or severity of the abnormal fetal heart rate pattern or the degree of acidosis before delivery.

Details of the operative procedures were obtained from dictated, typewritten, operative notes, which were required on all midforceps and cesarean deliveries. Information regarding the neonate was obtained from a copy of a pediatric newborn assessment form that was contained in the mother's chart. In those instances where morbidity was recorded, the newborn's chart was reviewed in detail.

Approximately 90% of the deliveries were performed by the resident staff under the supervision of full-time faculty members. The remainder of the operations were performed by full-time or visiting faculty members on their personal private patients.

The mean and standard deviation for age, parity, birth weight, length of second stage of labor, epidural anesthesia during labor, oxytocin augmentation, and hospital days were calculated for each group. Neonatal outcome was assessed by Apgar scores, arterial and venous cord blood gas values, admission to the neonatal intensive care unit, and birth trauma. Umbilical cord blood gas values were tabulated only for the last 2 years of the study because, before that time, samples were identified merely as "cord blood" with a single pH value. During the last 2 years, complete blood gas analyses for both arterial and venous blood were available in approximately 50% of the study patients. Maternal outcome was analyzed with respect to blood loss, febrile morbidity, intrapartum and postpartum complications, and the frequency of blood transfusions. Blood loss was estimated by the change in hematocrit (percentage points) between admission and the first day post partum in nontransfused patients. Febrile morbidity referred to a temperature of ≥38° C or more that appeared after the first 24 hours post partum and necessitated antibiotic treatment. The majority of patients undergoing cesarean section received prophylactic antibiotics. Statistical significance of the differences in means was calculated with the standard t test or by Fisher exact analysis.

Table I. Primary indication for operative delivery

	Midforceps	*Cesarean delivery*
Dystocia	171*	207
Fetal distress	187	279
TOTAL	358	486

*Occipitotransverse, $n = 94$; occipitoposterior (right or left), $n = 77$

Results

The primary indication for the operative deliveries is indicated in Table I. The incidence of midforceps and cesarean section deliveries in the study group was 1.9% and 2.6%, respectively. During the same time period, the overall cesarean delivery rate was approximately 16%.

The profiles of the study populations are shown in Tables II and III.

A comparison of midforceps and cesarean section deliveries in the dystocia group (Table II) revealed differences in the means for birth weight and the duration of the second stage of labor. The use of epidural anesthesia was comparable in the two groups, but a greater percentage of patients undergoing cesarean delivery required oxytocin stimulation of labor. Parity and change in hematocrit were not significantly different between the two groups, but hospital stay was longer in the cesarean delivery group.

The differences in variables in the fetal distress group were similar to those observed in the dystocia group with the exception of the mean age of patients. Blood loss, as reflected in change in hematocrit, was greater in the cesarean delivery group.

Apgar scores ≤4 at 1 minute and <7 at 5 minutes are shown in Tables IVA and IVB. Significant differences in Apgar scores after midforceps or cesarean delivery were noted in the fetal distress group but not the dystocia group.

Data concerning umbilical cord arterial and venous blood gases are shown in Table V and VI. There are no significant differences in averaged values for pH or base excess when midforceps and cesarean deliveries are compared. However, there is a greater degree of acidemia in the fetal distress group than in the dystocia group regardless of the method of delivery. There are a greater number of neonates with pH < 7.10 in the midforceps group, compared with cesarean deliveries for management of dystocia, but differences are not significant.

<7 at 5 min	2	10	<0.001

Operative and postoperative maternal complications associated with the method of delivery are shown in Tables VII and VIII. The third- and fourth-degree extensions and uterine extensions are unique to the method of delivery and could not be compared. Febrile morbidity was significantly increased ($p < 0.001$) and the need for blood transfusions was three times greater in the cesarean delivery patients ($p < 0.001$).

The short-term neonatal complications are depicted in Table IX. There were no neonatal deaths. There were no skull fractures or seizures noted in the records. Included in the shoulder dystocia cases was one infant with a fractured clavicle. In approximately 50% of cases, admission to the neonatal intensive care unit was for observation or to rule out sepsis.

Comment

Uncertainty regarding the safety of midpelvic forceps delivery stems from conflicting reports of neonatal morbidity. Cooke[4] reported a number of serious complications including skull fracturs, seizures, and central nervous system depression in 429 midforceps deliveries. Hughey et al.[7] compared 458 midforceps deliveries with 17 cesarean section deliveries performed for similar indications and noted a 30% neonatal morbidity in the forceps group compared with 0% with cesarean section. Chiswick and James[8] reported significantly greater neonatal morbidity in neonates delivered by midforceps than in a control group who were delivered of their infants spontaneously. Bowes and Bowes[9] compared 71 midforceps deliveries and 37 cesarean sections performed because of a prolonged second stage of labor and reported 19% and 5% neonatal morbidity, respectively. Dierker et al.[5] found no evidence of greater neonatal morbidity with midforceps compared with cesarean section when the indication for delivery in both groups was dystocia or fetal distress. Traub[6] compared 132 Kielland forceps deliveries and 20 failed Kielland deliveries with 101 cesarean sections performed during the second stage of labor and could find no increase in neonatal morbidity in either forceps groups.

The reasons for the differences between these reports concern the difficulty of the midforceps deliveries and the comparison of midforceps with other routes of delivery. Older studies, which describe excessive

trauma and neonatal morbidity, were associated with a high incidence of "difficult" midforceps deliveries performed at high stations, sometimes requiring multiple attempts at rotation and traction before delivery was accomplished. As a consequence, midforceps deliveries at station 0 or +1 are rarely attempted in current obstetric practice. Neonatal outcome after midforceps delivery was compared with that after other methods of delivery when there was no valid basis for comparison. A realistic comparison of midforceps delivery requires that the alternative methods of delivery be appropriate under the circumstances.

Dystocia group. The increase in the length of the second stage of labor and the high percentage of oxytocin stimulation of labor in the dystocia group are expected findings. The difference between the midforceps and cesarean delivery groups with regard to these two variables is probably of limited clinical importance. However, it is reassuring to note that the mean birth weight in the midforceps group is significantly lower than that in the cesarean section delivery group. The average length of the second stage of labor, which exceeded 3 hours, confirms the present tendency to allow the second stage to continue as long as there is no evidence of fetal distress.

Epidural anesthesia was used during labor in 65% of patients delivered by midforceps for management of dystocia. In the subgroup with transverse arrest of the fetal head, 94% underwent epidural anesthesia. Whether epidural anesthesia in labor contributes to the incidence of malposition or prolongation of the second stage of labor is unclear. Hoult et al.[10] found a fivefold increase in the use of forceps and a threefold increase in malpositions with epidural anesthesia. Johnson et al.[11] reported longer first and second stages of labor with epidural anesthesia. Friedman and Sachtleben[12] noted no increase in the frequency of malpositions or change in labor patterns with epidural anesthesia.

The anticipated difference in averaged blood loss between cesarean and vaginal deliveries was not observed probably because of additional bleeding associated with vaginal lacerations and episiotomy extensions in the midforceps group.

The condition of neonates at birth, as reflected by Apgar scores and cord blood gas values, indicates no apparent differences between the midforceps and cesarean groups. Number of hospital days was greater in patients delivered abdominally, as expected.

Fetal distress group. The significant difference in mean birth weight between the midforceps and cesarean neonates is again noted. The length of the second stage of labor was significantly less in the midforceps group than in the cesarean group. This difference and the increased percentage of low Apgar scores in the cesarean group probably results from the time required to prepare for and perform the abdominal operation. In addition, the use of general anesthesia for cesarean delivery also may have contributed to the number of low Apgar scores. A relationship between the low Apgar scores and cord blood gas values in the cesarean

Table VII. Maternal operative complications

	Midforceps (N = 358)		*Cesarean delivery (N = 486)*	
	n	%	*n*	%

Table VIII. Maternal postoperative complications

	Midforceps (N = 358)		*Cesarean delivery (N = 486)*	
	n	%	*n*	%
Febrile morbidity	14	4	122	25
Pulmonary embolism	0	0	2	0.4
Deep venous thrombosis	0	0	5	1
Blood transfusion	7	2	29	6

delivery group could not be shown. The lack of correlation between Apgar scores and the metabolic state of the neonate has been noted by others.[13-15] Moreover, Dennis et al.[16] also were able to show that the acid-base status and Apgar scores in 230 term births did not correlate significantly with neurodevelopmental outcome at 4½ years. In fact, the group of children with the highest degree of impairment were in the nonacidotic, low-Apgar-score group. The authors suggested that in the fetus the ability to produce an acidosis in response to labor may be an indication of well-being.

Maternal complications. Our data support an increase in maternal morbidity with cesarean delivery compared with midforceps delivery. Specifically there was an increased incidence of febrile morbidity and the occurence of deep venous thrombosis, pulmonary embolus, and more frequent need for blood transfusion. The increased febrile morbidity was noted even though 90% of patients undergoing cesarean section received antibiotic prophylaxis, compared with 5% of midforceps delivery patients. The lacerations and extensions of incisions were generally minor in both groups but in some cases did account for the need for blood replacement. The two patients with pulmonary embolus were discharged after appropriate medical treatment.

Table IX. Neonatal short-term outcome

	Midforceps (N = 358)		*Cesarean delivery (N = 486)*	
	n	%	*n*	%
Shoulder dystocia	7	2	0	0
Cephalhematoma	14	4	0	0
Facial palsy (temporary)	14	4	0	0
Admission to neonatal intensive care unit	21	6	19	4

The future morbidity of cesarean delivery, which should be considered, includes morbidity associated with repeat cesarean delivery, repeated blood transfusions, and the risk of uterine rupture.

Short-term neonatal outcome. Midforceps delivery did result in some trauma to the neonate, but the injuries were relatively minor and transient. There were seven shoulder dystocias, including one infant with a fractured clavicle. Erb's palsy, occurring in two infants, resolved before discharge and the facial palsies also were transient. The figure for admission to the neonatal intensive care unit for both the midforceps and cesarean section groups is probably low. Information regarding this event was obtained from a copy of the newborn assessment form, which was contained in the mother's chart. If admission to the neonatal intensive care unit was not noted on the form or occurred at a time after the initial assessment, the admission would have been missed. Of the neonates who were admitted to the neonatal intensive care unit, 75% were discharged in <48 hours.

Long-term neonatal outcome. No attempt was made to perform a long-term follow-up of the neonates in this series, but the subject has been extensively reviewed by Richardson et al.[17] Fuldner[1] and Eastman et al.[2] reported an increase in the incidence of cerebral palsy after midforceps delivery while Steer and Boney[18] found no such relationship. Friedman et al.[19] reported decreased Intelligence Quotient with midforceps delivery but neither Benaron et al.,[20] Corston,[21] nor Bishop et al.[22] could confirm this relationship. Dierker et al.[23] could not find a significant difference in the incidence of neurologic deficit between midforceps and cesarean delivery peformed for management of dystocia or fetal distress.

It must be acknowledged that there are weaknesses and limitations to the retrospective design used in our study with its inherent nonrandom method of assignment. A number of factors that enter into the decision to perform midforceps or cesarean deliveries were not controlled. These include station of the fetal head, estimated fetal weight, size and shape of the maternal

pelvis, severity of fetal distress, condition of the mother, and the degree of enthusiasm of the residents and faculty members to attempt midforceps delivery. Some appreciation of the impact of these factors on the decision as to the method of delivery can be gained from the following tabulation of the incidence of midforceps deliveries in selected series: Dierker et al.,[5] 0.8%; Bowes and Bowes,[9] 1.2%; Dunlop,[24] 5.1%; Gilstrap et al.,[15] 7.3%; Danforth and Ellis,[25] 12.9%; this series, 1.9%.

Another potential weakness of our study could be that the exclusion of failed forceps deliveries obscured instances of significant trauma to the neonate or the mother. Although this possibility cannot be ruled out, Traub[6] found that neonatal outcome after failed Kielland forceps delivery was not different from outcome after successful Kielland's or cesarean delivery.

The safe use of midforceps requires a systematic approach to proper patient selection and the recognition of factors that are important in minimizing neonatal trauma. During the course of our study, an attempt was made to adhere to the following guidelines as a means of ensuring the prudent use of midforceps: (1) ascertainment of a clinically adequate pelvis without prominent ischial spines, (2) verification that the fetal head fills the hollow of the sacrum, (3) assessment of the fetal head to confirm position and the degree of deflexion or asynclitism, (4) use of adequate anesthesia, (5) presence of an individual with experience and skill in the use of midforceps, (6) application of forceps, rotation of the head, and descent with traction proceeds with ease or the procedure is abandoned, and (7) informed consent.

We conclude that the data presented in this study support the concept that midforceps delivery can be performed in carefully selected patients with no increase in significant, short-term neonatal morbidity and with a substantial decrease in maternal morbidity compared with cesarean deliveries performed under similar circumstances. We did not evalaute long-term neonatal outcome. The definition of midforceps proposed in an opinion by the Committee on Obstetrics of the American College of Obstetricians and Gynecologists published in 1988 was: "The application of forceps when the head is engaged but the leading point of the skull is above station +2." According to this definition, the present study would concern low forceps rather than midforceps, except for the two cases at +1. However, the definition is less important than the underlying principle. The use of forceps to cause rotation and downward movement of the widest part of the fetal head past the narrowest part of the maternal pelvis is a potentially hazardous procedure that should be performed with care by or under the supervision of a skilled operator. If the proposed definition removes some of the stigma associated with the use of midforceps without a loss of respect for the procedure, then the change may be appropriate.

Discussion

Dr. Gilbert A. Webb, San Francisco, California. The role of the use of forceps to effect delivery when the vertex is in the midpelvis in modern obstetrics has been a subject of much controversy. This has resulted in the virtual abandonment of the procedure from many obstetric practices. Many candidates for the board examination have no cases of midforceps deliveries listed. There has been a decline in the number of individuals who are teaching the procedure.

Healy and Laufe[1] surveyed 144 members of the Association of Professors of Obstetrics and Gynecology in 1981. They found that only 18% of residency training programs felt that teaching midforceps deliveries was very important and 47% felt it was important. Unfortunately as the number of faculty capable of teaching any procedure declines, the numbers of residents who are capable of performing that procedure also decline.

Dr. Bashore and his group are to be commended for continuing the use of and the teaching of this operative technique. Dr. Bashore also is to be commended for this very careful evaluation between comparable indications for the termination of the labor process. By selecting only those patients with complete cervical dilation, when the vertex was at station 0 to +3 and was either occipitotransverse or occipitoposterior when the decision was made to deliver, he has eliminated many of the variables that have confounded previous studies.

At the point he has selected there are only two methods of delivery available—cesarean section or midforceps. The study is thus very narrowly focused. His careful analysis of his data revealed that there is no significant incidence of neonatal morbidity with either method while the maternal morbidity with cesarean section is significant. The two incidents of pulmonary embolism were potentially life-threatening. The increased use of blood transfusions also is an increased risk to the mother. The prolonged hospital stay with cesarean delivery is also signifciant in today's climate of cost cutting.

I reviewed our private practice for the year 1988. Four of the five members of our practice are members of this society and all are trained in the proper use of forceps. Out of 547 deliveries 101 (18.5%) were by cesarean section. Of this 101 21 (21%) were done for dystocia and 15 (15%) were done for management of fetal distress. These represent 2.79% and 3.83% of the total deliveries. Seventeen patients were delivered by midforceps because of fetal distress (3.10%) and 42 because of dystocia (7.67%). There was one case with an Apgar score of 3 at 1 minute and 8 at 5 minutes in the forceps delivery for fetal distress group. This was the only case in either the cesarean section or forceps group with an Apgar score of ≤4. It was related to a nuchal cord. All of our midforceps deliveries would be classified as low by the new American College of Obstetricians and Gynecologists definition.

There were no neonatal complications. The only maternal complication was urinary retention in two patients, but his cleared after 48 hours of catheter drainage.

Comparison of our data with those of Dr. Bashore is not possible as they are not as focused. All midforceps deliveries were included (under the old definition) rather than the limited group of his, but our results do reinforce the safety of the procedure when it is properly selected and executed.

There is no doubt that midforceps deliveries are operative deliveries and must be thought of as such. Respect for the procedure, as in any operative procedure, is essential. Dr. Bashore states that most of the fetuses in the occipitoposterior position were delivered in that position by use of Kielland's forceps. I would ask why rotations to anterior positions were not done either by Kielland's forceps or a Scanzoni maneuver?

In looking at the maternal complications after the midforceps deliveries, no mention was made of bladder complications, namely, hematuria or atony. I would ask Dr. Bashore if he is aware of any such problems. I noted that he had three "inadvertent cystotomies" in the cesarean section group.

The American College of Obstetricians and Gynecologists' redefinition of forceps delivers would place all but two of Dr. Bashore's deliveries in the low-forceps groups, but he is very careful to point out that the change in the definition does not decrease the need for careful selection and expert technique in effecting safe delivery.

Dr. James Caillouette, Pasadena, California. I'd like to add a word of caution regarding morbidity statistics. Let's remember that what Dr. Bashore reported was the experience at the University of California, Los Angeles, Hospital. In my opinion policy for private practice should seldom be based on university hospital experience. To support this statement, I asked the infection control nurse at Huntington Memorial Hospital in Pasadena to tell me our infection rate for cesarean sections. Our cesarean sections show a 0.9% surgical wound infection rate. The nurse epidemiologist at the Los Angeles County–University of Southern California Medical Center told me that their current infection rate for cesarean section is 13.1%. I don't know the rate at

University of California, Los Angeles. However, I submit that university hospitals are apples and private community hospitals are oranges.

Dr. Howard Blanchette, Berkeley, California. I too am concerned about your definition of neonatal morbidity. You report one fractured humerus, 14 cephalhematomas, and 14 transient facial palsies. In the private sector there is certainly concern about "social" morbidity. You have to inform patients about these transient phenomena. Dr. Bashore, particularly with regard to facial palsy, could use of the vacuum have eliminated that component of morbidity? In our community, despite the fact that many of our obstetricians are solid practitioners with extensive experience with midforceps, there has been a rapid decline in the use of midforceps. Now virtually all use the vacuum rather than forceps for these deliveries.

Dr. Robert Goodlin, Denver, Colorado. I think we should be careful about the use of the term *failed* forceps. All of our obstetric textbooks describe this as something that should never happen. The expression should be a *trial of* forceps. I have tried over the years to teach all residents, before they become senior residents, the techniques of forceps rotation. Of the hundreds of people that I have worked with, I have yet to know one who says that out in the "real world" he still does these procedures.

Dr. Gainer Pillsbury, Long Beach, California. Dr. Goodlin, I am one of your residents who learned the use of forceps and was an enthusiast for several years. For the last 10 to 15 years, however, I have gone over to the vacuum extractor almost exclusively and find equally good results. Of course, I'm unencumbered with data to prove it, but I feel that I have equally good results with less maternal trauma.

Dr. Bashore (Closing). Dr. Webb, I suppose the tendency to rotate oblique posterior presentations to occipitoposterior ones is an institutional pecularity. The number of full-time faculty members who supervise the delivery room varies between 16 and 18 at any one time. Each has his or her own preference for a particular forceps procedure. Some posterior presentations were rotated to occipitoanterior ones by the Scanzoni maneuver and some with Kielland's forceps. Indwelling catheters were necessary after forceps rotation in some cases, but we did not tabulate the number.

Dr. Caillouette, the incidence of wound infection after cesarean section does vary between institutions. In those institutions with resident training programs and with a large percentage of nonprivate patients, there will be a higher rate of wound infection than will be noted in a private patient setting.

Dr. Blanchette, there is no doubt that facial palsy is a risk of forceps delivery, especially midforceps and especially with rotation. All of the facial palsy in our series was transient. I certainly agree with you that, had vacuum extraction been used, we probably wouldn't have had cases of facial palsy. The other side of that argument is that some of the vacuum extractions would have failed and cesarean section would have been necessary. Also it must be remembered that vacuum extraction has its own associated neonatal morbidity.

Dr. Goodlin, perhaps if we use the term *failed trial of forceps,* we would all be more correct. I'm sure that midforceps procedures are more likely to be performed in institutions with residency training programs. When residents go into private practice, the world does change. Dr. Roy Pitkin described to me a survey he performed when he was at Iowa, involving residents who had completed their training there more than 5 years previously (Pitkin RM. Personal communication). All had been trained in the use of midforceps. He asked two questions: (1) Were there indications for the use of midforceps in your obstetric practice? About 75% responsed "yes." (2) How many midforceps procedures have you done since you went into private practice? The answer was usually varied between "none" or "one" or "two." So even residents who were all trained in the use of midforceps are not using them in their private practice.

Dr. Pillsbury, I cannot resolve the question as to the use of vacuum or midforceps. This discussion will certainly continue. However, one must recognize that there is an incidence of morbidity associated with the use of the vacuum extractor.

Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries

Patricia A. Robertson, MD, Russell K. Laros, Jr., MD, and Rei-Ling Zhao, MD
San Francisco, California

A retrospective analysis of low-pelvic and midpelvic operative deliveries (according to the new definitions by the American College of Obstetricians and Gynecologists, 1989) matched with cesarean section deliveries of similar station was undertaken. In all vaginally delivered groups there was significantly decreased maternal morbidity, maternal hospital stay, and estimated blood loss. In the midpelvic deliveries, there was a significant increase in the frequency of neonatal resuscitation and an increase in base deficit for the umbilical artery. In both the midforceps and low-forceps groups, there was a significant increase of neonates with cord arterial pH <7.10, and an increase of base deficit, even when cases of fetal distress were eliminated. The midforceps group also had an increased rate of admission to the intensive care nursery and an increase in the risk of significant birth trauma. In considering a midforceps or midvacuum operative delivery, the potential associated risks to the neonate must be balanced against the benefits to the mother. (Am J Obstet Gynecol 1990;162:1436-44.)

Key words: Obstetric forceps, vacuum extraction, birth injury, newborn outcome

Amid increasing parental expectations for the "perfect baby," a markedly increased cesarean section rate, and the tense medical-legal climate, the controversy surrounding the role of vaginal operative delivery in modern obstetrics continues unabated.[1, 2] Although many studies have been published regarding vaginal operative deliveries, few have used control groups, and even fewer have been prospective, randomized trials.[3] In August 1989 the Committee on Obstetrics: Maternal and Fetal Medicine of the American College of Obstetricians and Gynecologists published an opinion[4] on obstetric forceps, redefining the concept of outlet, low-pelvic and midpelvic operative vaginal delivery, within a −5 to +5 scale system of station. On the basis of this new system of station and these redefinitions of outlet and low-pelvic and midpelvic operative deliveries, neonatal and maternal outcomes were studied to clarify the risks and benefits of midpelvic and low-pelvic operative vaginal delivery.

Material and methods

Four categories (midforceps, midvacuum, low-forceps, low-vacuum) of vaginal delivery were compared with matched cesarean deliveries in each category with a second stage of labor at least 30 minutes in duration. Neonatal and maternal outcome variables were identified with the computerized perinatal data base maintained by the Department of Obstetrics, Gynecology, and Reproductive Sciences at the University of California Medical Center at San Francisco, which contained 20,831 deliveries from November 1975 until December 1988.

First, the perinatal data base was adjusted to reflect the new definitions of station, which range from −5 (floating) to +5 (crowning) with the level of the ischial spines at 0, rather than the previous system of −3 to +3. The leading portion of the fetal skull now describes the level of station rather than the biparietal diameter or the caput. The data base was additionally adjusted for the new definitions of mid, low, and outlet vaginal operative deliveries by individual maternal chart review. Midoperative vaginal delivery is that in which the head is engaged, but the leading portion of the fetal skull is above a +2 station. Low operative vaginal delivery is defined as either station dependent or rotation dependent. Station dependent is when the fetal skull is at +2 station or below, with a rotation of 45 degrees or less. The rotation dependent category includes deliveries when the fetal skull is at +2 station or below, and the rotation exceeds 45 degrees. An outlet operative vaginal delivery occurs when the fetal skull is at +4 or +5 station, the scalp is visible at the introitus, and the rotation does not exceed 45 degrees.

After the perinatal data base was adjusted for the expanded definition of station and recategorization of mid, low, and outlet vaginal operative delivery, the data base was scanned for deliveries with the following cri-

teria: singleton pregnancies, cephalic presentations, gestational age ≥37 weeks, and second stage of labor longer than 30 minutes. Cases specifically eliminated were failed forceps or failed vacuum delivered, followed by cesarean section. Maternal variables studied included maternal morbidity, duration of intrapartum and postpartum hospital stay, the rate of blood transfusions, and the estimated blood loss at delivery. Neonatal variables included admission rate to the intensive care nursery, the number of days of ventilator use, the time to achieve sustained, spontaneous respirations, the necessity for active resuscitation at birth, Apgar scores at 1 and 5 minutes, the presence of birth injury, birth weight, and umbilical arterial and venous cord gas values (pH, base excess, P_{O_2}, and P_{CO_2}). Individual neonatal chart review was undertaken to define specific birth injuries.

The cases were selected and compared as follows: midforceps ($n = 95$) and midvacuum ($n = 52$) versus cesarean section, with a second stage of labor of at least 30 minutes at similar station ($n = 290$), and low-forceps ($n = 921$) and low-vacuum ($n = 347$) versus cesarean section of similar station and second stage >30 minutes ($n = 64$). The Bird modification of the Malmström vacuum extractor was used in the majority of the operative vacuum deliveries, rather than the softer silicone rubber cup. The categoric variables between the different groups were assessed by χ^2, and the quantitative variables were contrasted by Student's t test (SPSSX).

Results

The following maternal variables were significant at values of $p < 0.001$ in each category of mid and low operative vaginal delivery (both forceps and vacuum) versus matched cesarean section: decreased estimated blood loss, decreased intrapartum and postpartum hospital stay, and decreased maternal morbidity with the vaginal operative deliveries (see Table I). There was no significant difference in the rate of administration of blood transfusions between the different groups and the matched cesarean sections. Parity differed significantly only for the midforceps subgroup in which there was an increased incidence of nulliparous women in the cesarean section group.

In terms of neonatal outcome, there was only one neonatal death in the low-forceps group; death was a result of meconium aspiration. To show significant changes in perinatal mortality associated with the different modes of delivery, the sample size must be much larger than the data base used for this study. Thus this study focuses on neonatal morbidity.

Assessment of the neonatal outcome variables revealed that active neonatal resuscitation was significantly increased in both the midvacuum and midforceps groups compared with the matched cesarean sections even when corrected for fetal distress. In the low-vacuum group there was significantly more resuscitation required in the matched cesarean section group (possibly because of more difficult extractions at cesarean section). There was no difference in the rate of resuscitation in the low-forceps group compared with the matched cesarean sections (Fig. 1).

Table I. Significant maternal outcome variables in midoperative and low-operative procedures versus matched cesarean sections*

Method	*Mean estimated blood loss at delivery (ml)*	*Mean intrapartum and postpartum hospital stay (days)*	*Maternal morbidity (%)*
Midforceps	505 ± 240	4.17 ± 2.23	25.0
Midvacuum	455 ± 155	3.62 ± 1.56	32.1
Cesarean section	828 ± 251	5.58 ± 1.84	57.1
Low-forceps	456 ± 179	3.74 ± 1.63	32.8
Low-vacuum	456 ± 294	3.74 ± 1.25	32.8
Cesarean section	753 ± 293	5.60 ± 1.60	70.3

*Comparisons at $p < 0.001$.

The rate of admission to the neonatal intensive care unit was significantly higher for midforceps deliveries (Fig. 2). Correction for fetal distress did not eliminate the increase in admissions. There was no difference in the neonatal intensive care unit admission rate when low-forceps and low-vacuum deliveries were compared with cesarean sections. There were no differences in the following neonatal variables when the vaginal operative groups were compared with cesarean sections: the amount of time to develop sustained respirations, Apgar scores at 1 and 5 minutes (categorized as <7 versus 7 to 10), or number of days of ventilator use. Umbilical cord arterial and venous blood gas values are described in Tables II, III, and IV and in Fig. 3. Significant differences in pH include a doubling in the percent of neonates with umbilical vein pH values <7.20 in the midforceps group when matched with cesarean section at similar station. There is a similar, significant increase in the percent of infants with umbilical artery pH values of <7.10 in both the midforceps and low-forceps groups. Significant differences in base excess include an increase in arterial and venous base deficit in the midforceps and midvacuum deliveries versus the cesarean sections, and an increase in arterial and venous base deficit in the low-forceps group. These differences persist when cases of fetal distress are analyzed separately.

Table V describes the percent of associated labor abnormalities of each mode of delivery (active phase arrest, slow slope active phase, prolonged labor) and the respective mean lengths of the first and second stage

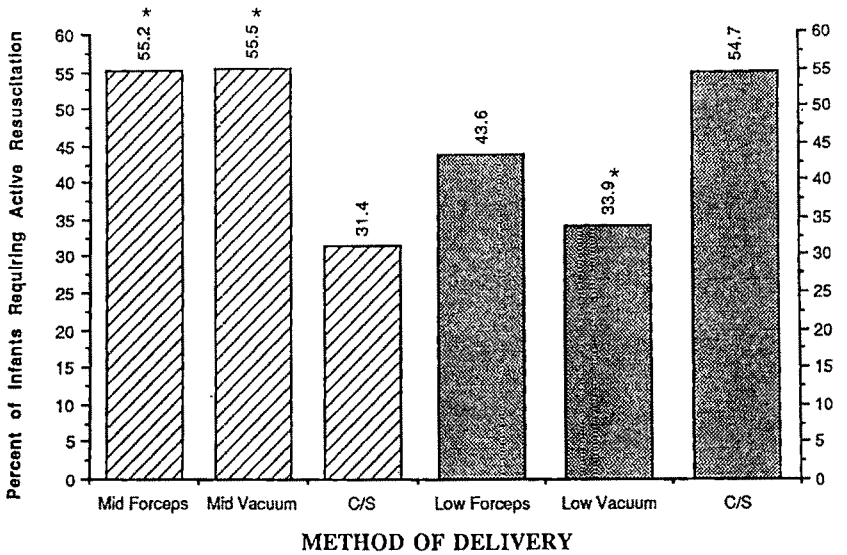

Fig. 1. Rate of active neonatal resuscitation.

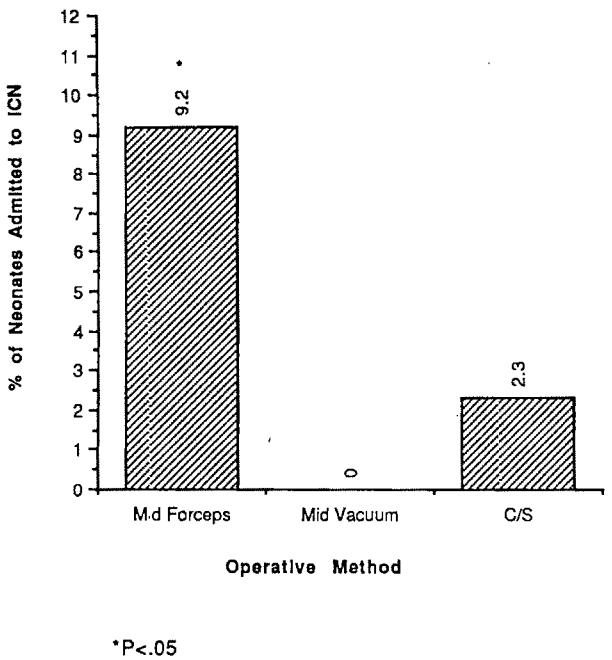

Fig. 2. Intensive care nursery admission rates for midoperative vaginal delivery corrected for fetal distress versus matched cesarean section.

of labor. Birth weights differed in two of the groups: the midforceps (3526 ± 482 vs 3642 ± 490 gm in the cesarean section group; $p < 0.05$), and low-forceps (3472 ± 461 vs 3602 ± 433 gm in the cesarean section; $p < 0.05$).

Table VI describes the incidence of birth trauma overall with the different methods of operative vaginal deliveries. Birth trauma was increased significantly in the midforceps and midvacuum deliveries compared with matched cesarean sections. However, the majority of the increased birth trauma in the midvacuum deliveries was a result of bruising. When bruising was eliminated as a category, the difference in the midvacuum category versus cesarean section disappeared. The difference in the midforceps group did persist at a $p < 0.05$ level of increased birth trauma (nerve, fracture, and significant "other"). The majority of the birth trauma with the midforceps groups was composed of nerve injury and fracture, with one additional case in the "other" category: a case of dural venous sinus thrombosis. This occurred in a case of a failed Scanzoni maneuver followed by a delivery with Kielland's forceps from an occiput posterior position at delivery. Of the 21 cumulative birth injuries, 10 were probably directly attributable to the instrument (eliminating clavicular fractures and Erb's palsies): four skull fractures, five facial nerve palsies, and one dural venous sinus thrombosis. Table VII describes the specific birth injuries according to method of operative delivery.

Comment

This retrospective study of mid and low operative vaginal deliveries matched with cesarean sections at similar stations is the first description of maternal and neonatal outcome using the newly published definitions by the Committee on Obstetrics: Maternal and Fetal Medicine of ACOG.[4]

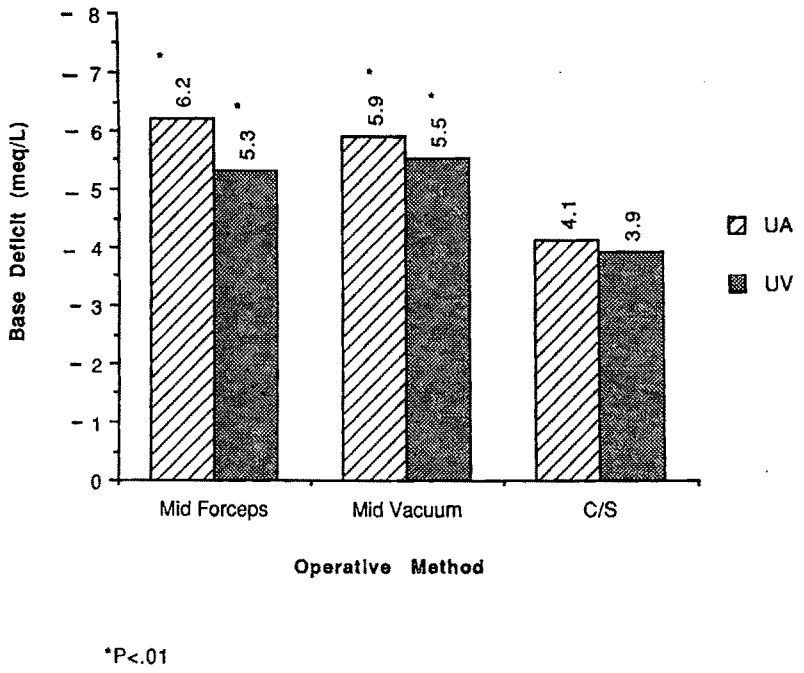

Fig. 3. Base deficit of umbilical cord gas values with midoperative vaginal delivery versus matched cesarean section.

The finding of significantly less maternal morbidity, less estimated blood loss, and decreased hospital stay with operative vaginal deliveries compared with cesarean section deliveries is in agreement with other studies.[5] In considering the operative methods separately, midforceps delivery had substantially more detrimental neonatal effects. These adverse outcomes were expressed as a significantly increased rate of admission to the intensive care nursery, an increased necessity for active neonatal resuscitation at the delivery, an increase in neonatal acidemia as reflected by increases in arterial and venous umbilical blood base deficits, and an increased risk of significant birth trauma (except from bruising). These differences are not explained by labor abnormalities or by fetal distress. In each category the matched cesarean section group had a higher incidence of active phase arrest, slow slope active phase, prolonged labor, and longer first and second stages of labor.

Midvacuum delivery also had adverse neonatal effects: an increase in resuscitation at the time of birth, an increase in arterial and venous base deficits in umbilical cord blood gases, and a significant risk of bruising from the application of the vacuum cap, which can result in an increased risk of cephalohematoma and jaundice.[6,7] In a recent publication Svenningsen[8] compared the slow pressure buildup of the vacuum with the rapid buildup, and found no significant alteration

Table II. pH of umbilical cord venous blood gases of operative vaginal deliveries versus matched cesarean sections

Method	*pH < 7.20 (%)*	*Significance*
Midforceps	34.6	$p < 0.01$
Cesarean section	15.1	—
Midvacuum	28.9	—
Cesarean section	15.1	—
Low-forceps	33.2	—
Cesarean section	22.8	—
Low-vacuum	18.8	—
Cesarean section	22.8	—

Table III. pH of umbilical cord artery blood gases of operative vaginal deliveries versus matched cesarean sections

Method	*pH < 7.10 (%)*	*Significance*
Midforceps	46.8	
Cesarean section	20.3	$p < 0.001$
Midvacuum	28.9	
Cesarean section	15.1	—

in the maximum force applied and a decrease in the incidence of cosmetic injury with the rapid technique.

It cannot be stated strongly enough that any attempt at midpelvic or low-pelvic vaginal operative delivery should be considered a trial and should be conducted in an environment in which an immediate cesarean section in the event of a failed procedure can be carried out, since neonatal outcome is adversely affected if there is a delay from the failed procedure to the delivery.[9] We eliminated failed forceps and failed vacuum procedures because of the difficulty of ascertaining all cases in which an attempted vaginal delivery failed. Inclusion of these cases could possibly have influenced the findings. However, it would be expected that these cases would show an even greater adverse neonatal outcome; this would only strengthen our conclusions. In contrast, the low vaginal operative birth appears to have marked maternal advantages, with little, if any, effect on neonatal outcome parameters.

Umbilical cord arterial and venous blood gas values have only recently been studied in relationship to mode of delivery. Gray and Nelson[10] describe three groups of neonates delivered by one of the following three methods: low outlet forceps without previous "mid-

pelvic forceps rotation," silicone rubber vacuum extractor with the only criteria of engagement of the fetal head and complete cervical dilation, and a group of patients who were delivered spontaneously. They found no significant differences among the groups in cord blood pH, P_{CO_2}, P_{O_2}, base excess, or bicarbonate values. Nickelson and Weber[11] found that delivery by vacuum extraction or low forceps resulted in lower pH and higher carbon dioxide tension, but that these changes were correlated with the indication for the procedure, rather than the procedure itself (i.e., when fetal distress was eliminated, there were no differences from spontaneous vaginal deliveries). It is interesting to note that in our findings of cord gas values, there was an increase in umbilical vein blood P_{O_2} in the low-vacuum and midvacuum deliveries and an increase of umbilical artery blood P_{O_2} in the midforceps and midvacuum group, despite increased acidemia in these latter groups. It is possible that this increase in P_{O_2} might be secondary to the Bohr effect (shifting of the oxygen affinity curve in the event of acidosis). Unfortunately, we did not measure oxygen saturation and thus cannot evaluate the Bohr effect. Because acidemia is associated with poor neonatal outcome, the decreased pH and increased base deficit are clinically more important findings.

The relationship of an increased base deficit reflecting fetal acidemia to encephalopathy has been described by Low et al.[12] In a study of preterm and term high-risk infants, the presence of a base deficit >30 mmol was significantly correlated with newborn encephalopathy (28% incidence, with 8% in the severe category). The long-term outcome of neonates from the different modes of operative vaginal delivery has been sporadically studied; the control group, if used at all, consists of spontaneous deliveries. Small follow-up studies of infants born by forceps[13, 14] and by vacuum[15, 16] deliveries have not shown significantly different outcomes but all studies except one[17] have been completed before the children were 6 years of age, when more subtle learning disabilities might appear.

Finally, the importance of the current ACOG schema for classifying instrumental vaginal deliveries into four rather than three categories is validated by comparison of our results with those of a previous study.[18] Our first study found no active adverse fetal effects attributable to the use of midforceps delivery (old definition). The matching technique of data analyses was identical in the two studies. Clearly, the old definitions of "low" and "mid" pelvic delivery added a large number of infants with excellent outcomes to the "mid" pelvic group, thus obscuring the true morbidity of this delivery mode. When a midvacuum or midforceps delivery is contemplated, the potential risks to the neonate must be carefully balanced against the benefits to the mother.

Table VII. Number of serious birth injuries associated with mode of delivery

Method	*Facial nerve palsy*	*Erb's palsy*	*Skull fracture*	*Clavicular fracture*
Midforceps	2	1	1	0
Midvacuum	0	1	0	0
Low-forceps	3	3	2	5
Low-vacuum	0	1	1	1

Discussion

Dr. John J. Molitor, Fullerton, California. The proper role and use of the obstetric forceps has been in contention since they were introduced, approximately 300 years ago. The pendulum of opinion has swung from one extreme to the other and is rarely in equilibrium. The literature is full of conflicting reports; some say midforceps are dangerous, others say they are not and that they still have a place in obstetrics. When neonatal outcome in midforceps deliveries is studied, one sees that most of the older studies are flawed because they were done before the widespread use of electronic fetal monitoring; thus there was no way to know the true condition of the infant before the midforceps delivery was used. In addition, there were no controls in the older studies. More recently, studies of this problem have matched the operative vaginal deliveries with cesarean section deliveries for similar indications. This study specifically matches operative vaginal deliveries with section deliveries, station for station, according to the new ACOG definitions. When I, and all of you who are my age received our obstetrics training, midforceps delivery was defined as delivery from 0 station down. Even if the head was almost on the perineum and if it was more than 45 degrees off the anteroposterior diameter of the pelvis, the delivery became by definition a midforceps delivery and was so coded on the chart. This was an impossibly large category, including simple forceps deliveries and those of great difficulty requiring consummate skill; all were classified as midforceps. In reality, most of the difficult operations resided in the fraction when the station of the head was between 0 and +2. With the new definitions, those deliveries are classifed as midforceps and the easier ones at lower station, even if requiring rotation up to 45 degrees, are classified as low-forceps.

Each time the obstetrician has to terminate a labor that is not progressing well, for whatever reason, he or she must make the decision to deliver vaginally or abdominally. This is always a judgment call and can be easy or extraordinarily difficult. Cesarean section is the "easy way out" but frequently does not serve the mother as well as a vaginal delivery would.

The data from this study show that cesarean section delivery imposed greater blood loss, longer hospital stay, and increased maternal morbidity when compared with operative vaginal delivery. I think estimated blood loss is extremely unreliable and subjective and that it is more likely to be underestimated in the case of a vaginal delivery than for cesarean section. In any event, there was no difference in the transfusion rates of the two groups. The length of stay figures are higher for both vaginally delivered and cesarean section patients than what we see here in southern California. I am surprised at the high morbidity rate of 70.3% of the mothers who had cesarean deliveries matched with the low-forceps and vacuum deliveries. I would like to ask Dr. Laros if this figure reflects just mild elevations of temperature or clinically significant infections? All of the above notwithstanding, I do not think those figures indicate that the mothers suffered any serious consequences of having a cesarean section rather than a vaginal delivery. What is more important, especially in today's litigious climate, is the welfare of the infants. The study figures show a significant increase in the frequency of neonatal resuscitation and an increase in umbilical artery base deficit for the midpelvic deliveries. In both the midforceps and low-forceps groups, there was a significant increase in the number of neonates with cord arterial pH <7.10 and an increase of base deficit. We have no long-term follow-up data on those infants and I leave to the experts whether or not this degree of acidemia would have any serious long-term effects. What bothers me most is the increased rate of admission to the intensive care nursery for the midforceps group and the increased risk of significant birth trauma for both the midforceps and low-forceps groups. Even though the incidence is different in the two groups, there are still traumatic injuries in the low vaginal delivery category as well as in the mid category. To the parents, traumatic injuries to the infant cannot be wished away, cannot be explained away as not statistically significant; they literally cannot be defended. If you ask any mother undergoing a labor that becomes complicated and requires a decision regarding method of delivery, she will tell you, "Doctor, do what is best for my baby." She will say this even though there may be some increase in risk to her own welfare. The most apprehensive mothers I have dealt with throughout the years are schoolteachers who work with developmentally disabled and handicapped children. As a father of a son with Down syndrome, I can appreciate their concern. The majority of available clinical evidence today shows that midforceps use exposes the fetus to harm.[1, 2] This study, in my opinion, corroborates that view even with the new definitions of the college. In the search for a newly defined category of "safe" forceps deliveries, I do not think you can balance the risks to the infant against the benefits to the mother; they are just too disproportionate.

The current incidence of midforceps deliveries as shown by papers presented here do not provide adequate numbers for training residents in this procedure. Furthermore, the risk to the infant does not justify more midforceps deliveries for training purposes.

It is time to acknowledge that midforceps delivery should be a thing of the past and that any forceps delivery, except perhaps outlet forceps by the new definition, should be approached with great caution.

DR. ROBERT A. SACK, Coarsegold, California. This year's program contains a paper discussing vaginal birth after cesarean section, another compares outcome in midforceps delivery and cesarean sections, and a third compares outcome in low-forceps and midforceps deliveries. These three papers, like so many in the recent literature, are directed toward reduction of the ever-increasing cesarean section rate. But do we really want to go back to the "good old days?" To attempt to answer this question, a paper presented before this society 21 years ago is now resurrected.

This was the study of maternal, obstetric, fetal, and newborn characteristics (including a long-term pediatric follow-up) of 766 infants who weighed 10 pounds or more at birth.

Admittedly, macrosomic infants represent less than 50,000 of the newborns delivered each year in this country; but these cases may serve to remind us of the mayhem committed in an effort to maintain a "respectable" cesarean section rate.

In this study the two major maternal complications were postpartum hemorrhage and shoulder dystocia. Seventy-eight mothers (10.3%) received at least one 500 ml transfusion of whole blood. Shoulder dystocia occurred in 76 deliveries (10.0%) and was lethal to the newborn in 29% of the cases. There was one maternal death.

One hundred fourteen (16%) of the infants were severely depressed at birth, all were apneic and required endotracheal intubation and artificial respiration for 2 to 60 minutes. Thirty-nine fetal deaths occurred (10 antepartum and 29 intrapartum). Sixteen infants were live-born but died in the nursery; the perinatal mortality rate was 7.2%.

Twenty-three (11.4%) of the 200 survivors who were followed up for an average of 5 years had a disabling neurologic problem. Nine (4.5%) died before the age of 7; six died in the first year of life.

A review of labor characteristics reveals that 39% of the mothers had a first stage of labor <6 hours and 87% had a first stage less than 13 hours. There was a second stage of labor less than 1 hour in 92% of cases.

Methods of delivery were as follows: spontaneous vertex, 76%; low-forceps, 6%; primary cesarean section, 5.2%; midforceps, 5.2%; and breech extraction, 2.8%. There were four destructive operations, two version and extractions, and one postmortem cesarean section.

As can be seen, almost every operative delivery known was used in the delivery of these unfortunate infants. I am certain that some methods are as foreign to the recently trained obstetrician as the Voorhees bag. They, and their patients, should be thankful.

One paper on this year's program refers to a prolonged second stage of labor and another refers to a second stage longer than 30 minutes. It might prove enlightening to evaluate the 8% of cases with a prolonged second stage in this series. In the 62 patients with a second stage longer than 1 hour, the following occurred: there were 22 cases of shoulder dystocia and nine infants died during delivery. There were three stillbirths, two destructive operations, and one death in the nursery as a result of sepsis. In this subset of cases there was a 26% perinatal mortality rate.

The study just presented was not done at the turn of the century. Unfortunately, I and a fair number of you in this audience, contributed to these statistics. In many training programs today a cesarean section may be the only operative delivery the residents are adequately trained to perform. To emphasize this fact, the report from the University of California Los Angeles notes 325 midforceps deliveries in 8 years. This number represents barely three such cases each month, and this number is not adequate to train a resident staff in the art of midforceps deliveries.

When the majority of residents leave training programs to enter private practice of obstetrics they are comfortable with and well trained in the performance of a cesarean section. This method of operative delivery is easy, safe, convenient and offers, by far, the least malpractice exposure.

The danger of the encouragement by consumer groups and organized obstetrics for vaginal birth after cesarean section may force some obstetricians into catastrophic situations they are not trained to handle. Two such examples would be the emergent need to perform a cesarean hysterectomy, bilateral hypogastric artery ligation, or both.

If, as is often intimated, cesarean sections are performed to increase the obstetrician's financial reward, there is a simple solution to the problem. On a relative value scale for obstetric delivery you need only to adjust the fee to reflect the degree of difficulty and the time expended. Vaginal deliveries would be paid 100% of scale, primary cesarean sections 75%, and repeat cesarean sections 50%. This plan is a sound one since it would eventually reduce physician charges but it would have little or no effect on decreasing the number of cesarean sections.

DR. DUNCAN NEILSON, Portland, Oregon. When we review the history of forceps development, we need to include the most recent development, one in the late twentieth century. In the late 1960s and early 1970s Dr. Leonard Laufe wrote extensively about reducing the morbidity of forceps operations.[1] He developed an instrument, now called the Laufe forceps, that significantly and measurably decreased the compression force on the fetal head. Those who teach residents to perform midforceps deliveries should read Laufe's

writings and teach the use of his instrument. My partners and I have found that it greatly facilitates the operation. I think this instrument can reduce the incidence of facial palsy. We simply do not encounter this problem, which is related to compression of the fetal head, in the infants delivered by midforceps any longer.

DR. JAMES CAILLOUETTE, Pasadena, California. Dr. Joseph Bolivar De Lee (1869-1942) championed managed labor with episiotomy and forceps delivery in an effort to achieve a perfect outcome. Let me quote a paragraph from a paper he read at the forty-fifth annual meeting of the American Gynecological Society, May 1920, which appeared in the first issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY that year.[1]

> Perhaps lacerations, prolapse, and all the evils women in labor are subject to, are, in fact, natural to labor and therefore normal, in the same way as the death of the mother salmon and the death of the male bee in copulation are natural and normal. If you adopt this view, I have no ground to stand on, but if you believe that a woman after delivery should be as healthy, as well as anatomically perfect, as she was before, and that the child should be undamaged, then you would have to agree with me that labor is pathogenic, because experience has proved such ideal results exceedingly rare.

The authors are to be commended for encouraging operative obstetrics. However, in my opinion the use of midforceps was an appropriate procedure in the early and mid twentieth century. Today the procedures of choice are low forceps and cesarean section.

To quote George Santayana (1863-1952), a contemporary of De Lee, "Those who fail to learn from the past are condemned to repeat it."[2]

DR. LAROS (Closing). The comment regarding estimated blood loss is certainly well taken. We did study the difference between the discharge and the admission hematocrit because this reflects blood loss. There is a difference and, as we all know, the difference is greater with cesarean section. We all underestimate blood loss regardless of the route of delivery. I agree with the comments on morbidity. Although the maternal morbidity is higher with cesarean section, it is usually not of long-lasting clinical significance. Conversely, I recall an unfortunate experience during my residency, a repeat cesarean section on a young woman who developed a pulmonary embolus and died 3 weeks after delivery. She continues to remind me that whenever you operate on anyone you present them with some risk.

The birth trauma issue truly is the major one. Having examined the data, we are now going back to the data set and attempting to "tease out" those factors that lead to significant fetal trauma. We hope to be able to identify those fetuses at risk and thus avoid traumatic injuries.

With respect to our teaching philosophy, I no longer teach midforceps delivery because I think that, except in certain instances of fetal distress, one should do a cesarean section rather than a midforceps or vacuum delivery from 0 or +1 station. However, I do take the advantage of the frequent use of epidural anesthesia to gain experience with low and outlet vaginal delivery. The house officer can learn all the techniques of proper application, ascertainment of position, and the proper method of extraction. As the house officer's experience grows, he or she becomes progressively more comfortable with forceps or vacuum extraction at higher stations. I frequently will say to a patient who has been pushing 2 to 3 hours and is still in an occipitoposterior position at +3 or +4 station, "Aren't you getting tired?" Many of them say "Yes." This situation provides an ideal opportunity to learn to use these techniques. Using these opportunities allows one to feel comfortable in an emergency situation to perform a truly indicated, emergency midforceps or midvacuum delivery.

Dr. Sack, I was impressed by your article when it was published. I have not knowingly delivered a patient whose infant weighed over 4500 gm vaginally since that time. This is a philosophy that we debate and consider on our service, but I'm very concerned about the risk of macrosomia. However, I carry in my head the thought that unfortunately two thirds of the cases of shoulder dystocia will come from infants under 4500 gm, so we are not safe, but certainly we can avoid these most difficult of situations.

Dr. Neilson, I have read Dr. Laufe's work and I apologize for not giving him credit. I learned to use Simpson forceps. Dr. Wilson, my teacher, allowed us to use only one kind of forceps—Simpson's. That was true also for breech cases. After you became proficient at delivering the aftercoming head with Simpson forceps, he might allow you to use Piper's forceps.

The placenta in the litigation process

Kurt Benirschke, MD
San Diego, California

The placenta accurately reflects many important prenatal events. It is therefore important that it be examined. This is especially useful in cases of possible future litigation, the "bad-baby cases." There is much experience now that pathologic findings in the placenta often have a decisive role in the accurate disposition of legal cases. This presentation describes the examination of the placenta and provides a brief review of the nature of placental lesions that most often impact cases of alleged malpractice. (Am J Obstet Gynecol 1990;162:1445-50.)

Key words: Placental examination, placenta and litigation

It is commonplace that the frequency of litigation regarding purported malpractice has increased. This has had a significant influence on the practice of obstetrics. The adverse effects vary widely from state to state. In addition to practitioners, medical students may have been influenced in seeking specialties other than obstetrics, for fear of future litigation.[1] It has been stated that 73% of fellows of the American College of Obstetricians and Gynecologists has had at least one lawsuit brought against them.[2]

One of the commonest reasons for litigation is an unexpected bad outcome of an infant, especially infants afflicted with cerebral palsy and those that die in the perinatal period. Inasmuch as cerebral palsy has no uniform cause, there is much room for argument in the courts as to possible deviations from the standards of practice or regarding true malpractice in the causation of cerebral palsy. Furthermore, many lawsuits are brought years after the birth of an afflicted child. This frequently makes it difficult to reconstruct accurately what the standards of practice were at the time of the child's delivery. It is often also impossible to ascertain disease factors, other than possible perinatal asphyxia, that may have had a role in the development of the neurologic disorder. For instance, possible prenatal infection with rubella virus, cytomegalovirus, or toxoplasma may be impossible to decide positively at a later date. Often, then, the witness is asked for his/her "best medical judgment," and the process is not necessarily interested in a statement of all the facts.

In addition to these vagaries, the expert witness is faced with the environment of the courtroom, to which few physicians are accustomed. This includes possible harassment by lawyers, endless postponements in courts, countless telephone calls, the review of voluminous records, and many more aggravations. The oft-asked plaintiff lawyer's question: "And how much do you charge for this testimony, doctor?" is also frequently sufficient reason for many well-meaning expert witnesses to withdraw from the whole scene altogether. This is much to be regretted, for he/she may have the only real answer to given questions—if indeed the process was seeking the real truth. But, to many of us, the legal proceedings are often executed much like a game, rather than as an honest search for the relevant facts. This is also frequently embodied in the nature of questions asked on the witness stand. And these may be unnerving, even raise one's anger.

Perinatal care is complex. It has greatly improved in recent years. Much new insight has been gained from chemical tests (such as maternal serum α-fetoprotein, human placental lactogen, amniocentesis); ultrasonography has ably displaced nearly all roentgenography of the fetus and is widely practiced with ever-improved machinery; neonatal care, resuscitation, and other measures have vastly changed over the years. One would think that cerebral palsy would have disappeared; it might, were it not such a complex disease.[3] An answer to the many questions this disease has raised was sought in a multihospital collaborative study of the 1960s. No simple cause was uncovered; in fact, the disease became perhaps more complex with this study. Thus Naeye and Peters[4] found that *chronic* rather than *acute* hypoxia, as is often suspected, has the greater influence on abnormal brain development. Similar findings have come from other studies, some of which clearly indicate that fetal brain damage may precede labor.[5, 6]

We have long maintained that a meaningful, thorough study of the placenta has much to offer in the understanding of perinatal illness.[7] Indeed, it has been my recommendation that all placentas should be ex-

From the Departments of Pathology and Reproductive Medicine, University of California San Diego.

amined, at least macroscopically, and that a record should be made of all placentas. Indeed, one may consider a technician's help to undertake this task. Since the rediscovery of the frequency of a single umbilical artery, most hospitals now require at least an entry into the maternal chart as to the number of vessels in the cord; a small beginning. But there is much other information to be had from a placental examination. In my view, the placenta is a reasonably good indicator of the maternal history, often a better one than can be obtained from the common "no prenatal care" admissions patient who is cared for in so many of our hospitals. It must be a knowledgeable examination, to be sure.[8]

During the course of the last 10 years, since malpractice lawsuits against obstetricians have increased so remarkably, I have often been asked to look at the record and histologic slides of placental examinations in cases of afflicted children. This has frequently been of material help in assessing the nature of the illness and in suggesting a possible cause of the disease. It has provided, at times, the deciding argument in complex cases. It is no wonder then that I still advocate a routine placental examination be undertaken.

Placental examination

A macroscopic placental examination takes only a few minutes, and when it is routinely practiced, the examiner becomes quickly familiar with the salient macroscopic findings. Several guides have been published to aid the novice.[9, 10] The examination is ideally done at the time of delivery, and the findings are then recorded in the patient's chart. When this is not feasible, the placenta should be stored until it has become certain that the infant has done well, usually 2 to 3 days. Storage is best undertaken in a labeled ice cream container, which is then refrigerated, not frozen. The morphologic features are well preserved for many days in such conditions, although some fluid loss occurs and the thickness of the organ decreases. I have found it most practical to store the placentas in a large refrigerator whose shelves are labeled with days of the week. As the refrigerator fills, the shelf of the previous week's day is emptied. We have never missed an important specimen in this way; it has always been available when the neonatologist requested an examination because of less than optimal outcome.

All placentas in cases of multiple births, congenital anomalies, children who are small for gestational age, or complicated and premature deliveries should be routinely studied. The selection of those that warrant histologic diagnosis requires experience and the cooperation of the local pathologist. It has also been my experience that availability of a good photograph of the placenta often would have provided crucial information when only a poor description was made. This is especially the case in placentas of multiple births.

The macroscopic examination should include the measurement of length of the umbilical cord, as well as its site of insertion; a verification of the presence of three umbilical vessels; an assessment of the membranes' color and of the sheen of the fetal surface; an assessment of the color shade of the villous tissue; an inspection for fetal vascular thrombi; an estimate of the percentage of infarction; an inspection for retroplacental or retromembranous clots; and, if possible, determination of placental weight (minus membranes and umbilical cord). In multiple gestation the cords should be labeled as to the sequence of delivery (A, B, etc.), the position of cords should be stated, the "dividing membranes" should be studied, and the nature of interfetal anastomoses (if present) must be identified. It is usually best to make a sketch of twin placentas.

Findings

It has been my experience, in cases of litigation for perinatal death and cerebral palsy, that placental examination has been most beneficial when the placentas were associated with: (1) multiple pregnancy, (2) prolonged pregnancy (especially relating to meconium staining), or (3) premature delivery and small-for-gestational infants.

Major additional positive findings to explain poor fetal outcome may include vascular thromboses, abruptio placentae, a single umbilical artery, abnormal cord insertion, the presence of many nucleated red blood cells in fetal vessels, chronic villitis, or maternal floor infarction. In many such cases the lack of a placental examination would have seriously impaired an accurate judgment in some litigations with poor fetal outcome.

Multiple pregnancy. Placentas in cases of twins have one of these configurations (higher multiples may have admixed chorionic status). In instances of a single cavity the placenta is monoamniotic, monochorionic (MoMo). In instances of two cavities the placenta is (1) diamniotic, monochorionic (DiMo) (always fused); (b) diamniotic, dichorionic, fused (DiDi); or (c) diamniotic, dichorionic, separated (DiDi).

A majority of dichorionic twins are dizygotic, and most of these gestations come to near term. Dichorionic twins have significantly fewer obstetric problems than monochorionic twin gestations. The really problematic cases have usually been monochorionic (DiMo or MoMo) twins. They are all monozygotic (identical).[11] Furthermore, because the excessive mortality of monochorionic twins relates to placental vascular connections, the surface vasculature must be accurately assessed. Also important is the recording of cord insertions (velamentous-marginal cords are much more common in multiple pregnancy). Finally, the possible

presence of "vanished twin" cavities or fetus papyraceus should be ascertained, as they may be an indication of earlier pregnancy disturbance.

One frequently arising question in litigation is whether a set of twins was afflicted with the transfusion syndrome. The classic twin transfusion syndrome is a very specific entity,[12] and it is easily supported by placental findings. Controversy still exists as to the best diagnostic parameters in this syndrome. It is often the cause of premature delivery, as a result of the hydramnios in the recipient's cavity. The arteriovenous anastomosis that is responsible for the syndrome is best recognized by careful injection of the vascular tree. Perhaps because of this syndrome, or for other reasons, monochorionic twins have a known relationship to prenatally acquired cerebral lesions.[13] One other aspect of great medicolegal importance is the influence that prenatal death of one twin has on the survivor, especially when the twins are interconnected by placental vascular anastomoses. Several cases of cerebral palsy in the survivor of monozygotic twins have been described after the original description of a neonate with widespread thrombotic lesions.[14] The mechanism of this phenomenon is not yet clearly understood. It is possible that thromboplastin from the dead twin infuses into the survivor, thereby initiating disseminated intravascular coagulation. We have also seen cases in which the inescapable conclusion was that placental emboli caused infarcts in the fetus. Alternatively, the sudden loss of "counterpressure" from the dead twin may lead to temporary near-exsanguination of the chorioangiopagous survivor, with consequent hypotension and possible central nervous system damage. In any case such placental evidence is of great importance, not only for our understanding of prenatal life but also for the proper adjudication in court. Massive shifts of blood from one twin to another often have been witnessed at delivery.

Prolonged pregnancy. In my experience, litigation of cerebral palsy cases involves postmature pregnancies more often than term infants. In such cases the question of meconium aspiration or the mere presence of meconium at labor is most commonly the pivotal argument. I have opined that green meconium is the "red flag" for plaintiff lawyers but that the cause of meconium discharge is poorly understood. It hardly ever seems to make an impression when I state that I have had to perform many autopsies on stillborn, term babies, dead of asphyxia, whose death was not accompanied by meconium discharge. Also, in my routine study of *all* placentas, more than 17% are meconium stained, while cerebral palsy occurs only rarely. Meconium is discharged by mature fetuses primarily as the result of a matured endocrine system; motilin seems to be a principal agent for its production.[15] Usher et al.[16] found that meconium discharge is more importantly related to maturity than to distress. It is probable, mainly for these reasons, that meconium discharge is much more common in postmature pregnancies than at term. It is extremely rare that premature gestations are associated with meconium discharge. When the membranes are green, this is generally due to the deposition of hematoidin, which has similar spectral absorption bands and which is often combined with hemosiderin. It should also be noted that, after prolonged meconium discharge, the pigment changes color, often becoming brownish.

Because meconium has played such a major role in litigation and because the timing of its discharge has been held to be of such importance, we have attempted to find out if time of discharge could be determined from the degree of staining.[17] Meconium can be ascertained grossly, and its bilirubin content can be seen microscopically in the macrophages of amnion and chorion. We found that within 1 hour yellow-stained macrophages appear in amnion and that it takes at least 3 hours before such staining reaches the chorion. This provides an approximate timetable, but it is of little real help in critical court cases. It has never before been appreciated that meconium, while perhaps occasionally discharged *because* of asphyxia, may in itself be a toxic substance. Pathologists see degenerative changes in the amniotic epithelium soon after meconium has been discharged, but when its vascular effects were studied in perfusion experiments of umbilical cords, it was found that meconium had a profound vasocontractile effect.[18] Thus meconium discharge is complex. It may follow asphyxia but does not necessarily do so. Once discharged, it may become a cause of further prenatal oxygen restriction because of the vasoactive factors.

Premature delivery and small-for-gestational-age infants. Cerebral palsy is more common in prematurely delivered infants. In part, this is due to a much greater frequency of cerebral hemorrhages in premature infants; however, it may also be the result of the complex causes that initiate premature delivery. A major finding in the placentas of spontaneous deliveries between 20 and 30 weeks of gestation is chorioamnionitis. The amniotic sac infection syndrome may be caused by many microorganisms; the pus may be aspirated, and fetal pneumonia and sepsis are frequent results. Good evidence is accumulating that ascending placental infection causes labor, is frequently present before rupture of membranes, and may have a devastating impact on fetal well-being. Much depends on the nature of the offending organism, infection with group B β-hemolytic streptococci being one of the most serious complications of perinatal life. Not only is fetal infection of potentially devastating consequence in postnatal life, but evidence is accumulating that inflammation of the umbilical vessels per se may cause their contraction

and thus perhaps reduce placental venous return.[19] In some infections, notably group B streptococci, it is equally possible that the bacterial toxins, rather than inflammatory cells, cause vasocontraction. Inflammation of membranes and cord is readily apparent by placental examination. Moreover, superficial mural thrombosis of fetal vessels is a frequent and important concomitant.

Growth retardation, not to be confused with prematurity, may have a specific placental cause that is also best identified by placental study. Thus the maternal vascular lesions of preeclampsia and the similar lesions caused by the presence of lupus anticoagulant may significantly reduce fetal growth. Maternal floor infarction[20] is an uncommon but often repetitive cause of severe fetal growth retardation that can be ascertained only by placental study. The cause of this disease has remained elusive, as has the cause of most instances of the much commoner "chronic villitis of unknown etiology."[21] Nevertheless, these are important placental lesions that necessitate the study of this tissue. Finally, fetal surface vessel thrombi are much more common than is generally appreciated. Their cause often remains undetermined, but they clearly indicate some antenatal disturbance that may have as much significance for fetal development as is now obvious for the finding of a single umbilical artery.

Many more pertinent findings come from expert placental examination, too numerous for this brief review. I will mention only the identification of nucleated red blood cells, the anemia that is grossly visible as pallor and that may be due to transplacental hemorrhage, the presence of chorangiosis (testifying to prolonged fetal problems),[22] and many more lesions that have excellent correlation with perinatal asphyxia and with events that often long precede delivery. They should be sufficient to mandate that placental examination be practiced more routinely.

Discussion

DR. JAMES A MERRILL, Seattle, Washington. The placenta is a human organ with an entire life span of approximately 9 months. During this time it functions as an enzyme factory, an organ of internal secretion, and an organ of transfer for the growth and developmental needs of the fetus. The importance of placental function in fetal development is well recognized. It is reasonable to expect the placenta to reflect both maternal and fetal disease states, yet the placenta is usually discarded after delivery—occasionally looked at but rarely examined in a careful manner. Dr. Fredrick (Fritz) Irving, anonymous author of ribald ballads and Professor of Obstetrics at Harvard Medical School, is quoted as remarking: "I have looked at thousands of placentas but have never examined one."

While many abnormalities of the placenta have been described, including the developmental and aging changes, interest in pathologic conditions of the placenta has not been overwhelming, and today still too little is known of the relationship of many placental lesions to fetal development and welfare. This is not

something that lends itself to planned prospective experiments. Moreover it is difficult to know if observed placental changes precede or follow adverse events in the fetus. Dr. Benirschke previously has stressed the importance of careful scrutiny of what he calls "the experiments of nature." Data are increasing to confirm that many neonatal neurologic disabilities have their origins antenatally, well before the onset of labor.

Dr. Benirschke recommends that placentas be examined routinely and, if not, that all placentas be stored, not frozen, for subsequent examination if the infant does not do well. Viewed from the perspective of personal interest and training, I certainly agree with this recommendation. Moreover, since the examination ideally is done at the time of delivery, I do not believe it is unreasonable to expect the obstetrician to accomplish a careful gross examination of the placenta and to record it in some organized fashion. Weight and measurements are important. Since intelligent examination must include adequate clinical data, the obstetrician has an advantage over the pathologist. I regret the deemphasis of pathology training. I believe that education in both gross and microscopic pathology of the placenta should be included in residency training. The practice of careful examination of the placenta in the delivery room may yield clinically helpful information such as a missing cotyledon or the presence of a succenturiate lobe, a fresh retroplacental clot of abruptio placentae, membrane rupture at the margin of the placenta (confirming the diagnosis of low implantation), significant infarcts, or even a rare chorioangioma.

Some authors have suggested, in lieu of routine examination of all placentas, that any obstetric or medical complication of pregnancy and fetal or newborn abnormality constitutes an indication for pathologic examination of the placenta. Dr. Benirschke singled out only a few complications and indicated that the selection of placentas for histologic diagnosis requires experience. Would he expand on specific indications for histologic examination of the placenta, if not routinely done?

Although desirable, there are some problems with routine pathologic examination of all placentas. The most obvious is cost. The majority of patients, those who are delivered of healthy babies, would be asked to bear an increased cost. This would not be the first example of cost for preventive and defensive medicine, however, and is less expensive than some of our new technologies. Another problem is the paucity of interested pathologists. In my experience few surgical pathologists have the training or the interest to examine many placentas. How can this be changed? Further, I see a need for greater investigation of the correlation between placental abnormality and perinatal abnormalities and outcome. For example, how good is the correlation between the finding of chorangiomatosis and fetal hypoxemia or other stress? What about hemorrhagic endovasculitis? To the extent that we can, it is important to correlate the structural and morphologic features of the placenta with perinatal loss, morbidity, and abnormal placental physiologic characteristics. At a time when every baby born is expected to be a perfect baby, this takes on new importance!

I thank Dr. Benirschke for offering a clear presentation of a topic that warrants our thoughtful concern.

Dr. Theodore Loring, Eureka, California. As an individual involved with a mutual insurance company, I find this subject dear to my heart. Dr. Benirschke, please comment on the work by Dr. Sanders from Michigan State, on what he called endovasculitis of the placenta.[1] Unfortunately, his material was published in a pathology journal and most of us in obstetrics have not had an opportunity to see it. Please also comment on the extensive work on the placenta by Dr. Naeye[2] from the University of Pennsylvania. For awhile, the companies insuring obstetricians were very pleased and hoped that the changes described by these two investigators could assist them in defending cases involving brain-damaged infants. However, I have heard nothing about their work for some time.

Dr. Merrill noted that one of our problems is that in very very few areas do we have anyone who would know anything about the placenta. My company is attempting to do something about this by urging all of our insured, some 500 or 600 people, to save a piece of the placenta and a portion of the cord with blood in it in any case where the Apgar score is under 9. We hope that perhaps we can come up with information that can help us with the defense of cases involving brain-damaged infants.

2. Naeye RL. Functionally important disorders of the placenta, umbilical cord, and fetal membranes. Hum Pathol 1987;18:680-91.

Dr. Russell Laros, San Francisco, California. Dr. Benirschke, I was very interested in your comments about the anastomotic vessels and have a three-part question. (1) When one has a set of monochorionic twins with the intrauterine death of one twin, how frequently does the survivor become affected by disseminated intravascular coagulation? (2) When this occurs, knowledge of the time available is of critical importance to the perinatologist caring for these patients. How wide is the window of opportunity for intervention? (3) How does the clinician decide when the survivor is truly at risk?

Dr. Benirschke (Closing). Dr. Merrill, yes, indeed, I think the placenta is underevaluated. It is very difficult to anticipate what pathologists will actually do because they do not have the patience to find out what is normal. It is easy for a pathologist to learn what normal skin is. He sees skin and skin diseases all day long. He will not ever see the variations of the normal breast or placenta. They all look different, and to understand what is a truly meaningful abnormality re-

quires that one see a lot of normal cases. That is the main reason why, when a placenta is sent for evaluation, the pathologist sends back a diagnosis of a mature placenta. He doesn't really know what it is and he doesn't have the patience to go through the thick stack of books that we have written to find out. It is important that the obstetrician examine the placenta in the delivery room and communicate to the pathologist what to look for.

Which placentas should be chosen for microscopy? Placentas of babies that have poor outcomes should be. Those of severely premature babies should be also because of the frequent finding of infection. I personally think all twin placentas should be examined microscopically. Is that, perhaps, asking too much? We have about 5000 deliveries a year now at University Hospital and I do between three and five microscopic examinations of placentas each week. That's not a very large number of placentas for a pathologist to look at and he would gain knowledge quickly.

It is easy to make a photographic record of the placenta in the delivery room by taking a Polaroid photograph and placing it in the record. This is much better, particularly in the case of twins, than a poorly written description of where the umbilical cord was inserted.

Dr. Loring, and I think also Dr. Merrill, mentioned endovasculitis. I don't believe endovasculitis exists. It is a nonentity in my opinion. There have been very good articles written on systematic degeneration of the endothelium and intermixing of blood with the vascular wall in placental explants in vitro. This is a phenomenon that occurs after fetal death. When the baby dies, the vessels of the placenta disintegrate and come to look like the description of endovasculitis. The reason you don't hear much about it anymore is that it doesn't exist.

Dr. Laros, I don't know the proportion of cases with disseminated intravascular coagulation. When there are large anastomoses and one twin dies, as many as 10% to 20% have this phenomenon. A hundred years ago, one of the famous Siamese twins Chang and Eng was alcoholic and the other was not. The former contracted bronchial pneumonia and wanted to sit up while his twin wanted to lie down. Chang died and Eng said "I'm going to die too" and, almost immediately, he died. At autopsy, done in Philadelphia, there were large anastomoses noted between the twins but there was no systematic investigation of this finding. In the future, perhaps, flow velocimetry will tell us something of the umbilical cords in circumstances when one twin dies and the other survives. We should be alerted to make the diagnosis of anastomosis of surface vessels by flow velocimetry. It is very difficult to ascertain on the placental surface but you can do it in the umbilical cord if you are skilled. We will be able to see changes in the flow pattern of a baby who survives. In my opinion the degenerative event is almost immediate. It takes but an hour or two. The question I will be asked soon, as an expert witness in court, is, "If the doctor had done a cesarean section as the patient came in, would the other twin not have suffered?" Perhaps the damage would be not as much, but the disseminated intravascular coagulation event would have taken place. Recording the hematocrit in those twins with massive shifts, I think, is important. It is important for us to learn how long it takes for a 2000 gm baby to have a shift of hematocrit from 50% to 30% or 20%. How long does it take for the blood to thin? We don't know yet whether we can judge from the hematocrit the length of time elapsed before the hemorrhagic event took place.

I don't know which babies are at risk. We never see this problem in diamniotic-dichorionic twins. We never see it when one umbilical cord is so twisted that no reflux of the other baby's "bad blood" is possible. We don't see it when there is a knot in the umbilical cord. It is possible, in some cases, to anticipate it. In the future we should learn how to classify the dividing membranes clearly and to separate the diamniotic-dichorionic placentas, which are at no risk, from the diamniotic-monochorionic placentas, which are at risk. There is a magnificent piece of work going on at Utah that will be published soon. Dr. Julian De Lia has successfully done laser fulguration of connecting blood vessels between monochorionic twins with the transfusion syndrome in three cases.[1] There was immediate cessation of hydramnios and the other abnormal events. You can anticipate that we will be able to coagulate vessels and prevent this syndrome from appearing.

Hysterectomy: A medical-legal perspective, 1975 to 1985

John M. Whitelaw, MD
Sacramento, California

Since 1975 the crisis in professional liability has been the most important problem affecting the future of obstetrics and gynecology. Increasing numbers of physicians have stopped delivering babies and most obstetricians have decreased their high-risk obstetrics. Most of the attention in the specialty has been directed toward the liability problem in obstetrics as opposed to gynecology. The liability problem in gynecology is not insignificant, however, and has increased in importance in the last several years. This is particularly true in the areas of failure to diagnose and complications of surgery. This study reports on the closed cases involving hysterectomy from Norcal Mutual Insurance Company, a physician-owned mutual company founded in Northern California in 1975. A number of factors are analyzed in comparing those cases involving payment of money because of a settlement or loss at trial with those cases in which no money was paid. (Am J Obstet Gynecol 1990;162:1451-8.)

Key words: Hysterectomy, malpractice, standard of care

The malpractice crisis is now 15 years old. Since 1974, we have witnessed a dramatic increase in liability insurance premiums for obstetrician-gynecologists. We have also witnessed the profound effect the crisis has had on the physician-patient relationship, often turning it into an adversarial nightmare.

A direct result of this crisis is the large insurance premium obstetrician-gynecologists now must pay. In 1975 many insurance companies stopped writing malpractice insurance policies, and in California physicians were faced with the prospect of being unable to buy liability insurance at any cost. A number of physician-owned mutual insurance companies were started at that time. One of these, which focused on the Northern California market, was Norcal Mutual Insurance Company (Norcal). The company has been successful and is now marketing in Southern California and Oregon.

Professional liability is the most serious problem facing the practice of obstetrics and gynecology. It has been responsible for increasing numbers of physicians seeking early retirement, dropping obstetric practice, and reducing high-risk care. A total of 73% of obstetrician-gynecologists have had at least one professional liability suit filed against them according to a survey conducted by the American College of Obstetricians and Gynecologists.[1]

Much of the emphasis on risk reduction in obstetrics and gynecology has been focused on obstetric practice with its long exposure and potential for high awards. Less attention has been aimed at the gynecologic aspects of practice that have risk potential for lawsuits. The fact that hysterectomy is one of the most commonly performed operations in the United States means that there is a significant potential for lawsuits—a fact that has certainly been noted in the legal literature.[2] This report evaluates the Norcal experience with hysterectomy-related malpractice claims. The impact of "standard of care" and other factors on the likelihood and amount of recovery is determined.

Methods

All closed claims involving hysterectomy for gynecologic indications were reviewed. The time period covered by this report is 1975 to 1985. Cases involving hysterectomy for obstetric complications, i.e., intractable hemorrhage, were excluded. Also excluded were hysterectomy claims related to complications of elective abortion.

The data were collected on a questionnaire developed to be used with a closed-claim master file. Typically, a closed-claim file consists of the pertinent hospital and office records, narrative statements of the defendant, as well as other involved health care personnel, expert and peer reviews, investigator's reports, attorney summaries, deposition summaries, and outcome reports. The completed case summaries included information on patient characteristics, third-party payor, location of venue, preoperative diagnosis, consent to surgery, and treatment alternatives used. Information was collected on the operative procedure, complications, pathologic results, and postoperative course. Data also were gathered on any injury, subsequent readmission and/or reoperation, degree of disability, and whether the injury was temporary or permanent. Finally, data were collected on the lawsuit itself, including the

amount of award or settlement and the cost to the company to defend the suit.

The overall appropriateness of care and its contribution to the mishap were evaluated. Particular attention was given to the evaluation of the county medical society medical review audit committee and to the evaluations of expert witnesses and claims reviewers. In the few cases where those reports were not available, I made an assessment of the appropriateness of care (I have substantial claims and peer review experience). Appropriate care was defined as that meeting the standard of practice for the prudent gynecologist in California. Inappropriate care was defined as that falling below the standard of practice. Care was judged inappropriate if the consent was not documented, if alternative therapies should have been tried and were not, if consultation should have been obtained and was not, and if complications occurred and were not fully documented in the chart and the patient informed.

Each claim was assigned a severity of injury score based on the company's eight-point scale. This scale rates each claim from 1 (no injury) to 8 (death). Values 1 to 3 represent minor, nondisabling, temporary injuries. Value 4 is a major but temporary injury; 5 and 6 are permanent injuries, and 7 is a grave injury. Table I lists each severity category with an example and the number of cases in each category.

A total of 262 claims involving hysterectomy were available for review. After obstetrics-related claims, abortion-related claims, and claims that were not yet closed were eliminated, 87 cases remained for review and they form the basis for this report.

Results

A summary of the frequency of allegation or injury is presented in Table II. Urinary injury generated 37 lawsuits, with alleged unnecessary hysterectomy the next most frequent with 15 cases. Of particular note is the fact that five cases resulted in the patient's death.

An obstetrician-gynecologist was the surgeon in 79 of the cases (90.8%) and was board certified in 65 of those 79 (82.3%). Of the remaining eight cases, five were performed by a general surgeon and three by a family physician with major surgery privileges. No gynecologist was involved in any of those eight cases.

Thirty-four of the 87 (39%) lawsuits resulted in an out-of-court settlement or jury award to the plaintiff. Patients under 30 years old received payment in 58% of cases; 36% of patients aged 30 to 49 received payment. Patients on welfare accounted for 30 of the 87 claims (34.5%),and 12 of them received payment (32.5%). Fifty-seven patients had other insurance or were self-insured, and 22 lawsuits were successful, about the same percent as for the welfare patients.

The likelihood of payment to a patient was greater if the standard of care was not met (Table III). Overall, the standard of care was judged to have been met in 59 of the 87 cases (67%). Of the 28 cases in which the standard of care was not met, 20 received payment (71%). Eight received no payment even though the standard of care was not met. Conversely, in the 59 cases where appropriate care was rendered, 14 patients received payment (23%). A total of 77% of patients treated appropriately who filed lawsuits received no payment.

The amount of payment to the patient depended on age, severity of injury, and appropriateness of care (Table IV). Patients under 30 years old received an average payment of $101,600, with a range from $6000 to $250,000. Patients aged 30 to 49 received an average of $46,900, with a range from $1000 to $250,000. Thus payment was likely to be higher if the patient was under 30 years old when the lawsuit was filed. Two large settlements ($250,000) for unnecessary hysterectomy in young patients influenced this finding.

As shown in Table V, payment increased with severity of injury. In category 2 (insignificant injury) one of five

patients received payments. An amount of $125,000 was paid in settlement to a 32-year-old multiparous woman who alleged unnecessary hysterectomy. This case is discussed later.

Of the 34 patients in category 3 (minor temporary injuries) 10 received money. The average payment was $11,386, with a range from $1000 (to a patient with a retained sponge that was removed abdominally immediately after a vaginal hysterectomy) to $29,999 (to a patient who suffered a rectovaginal fistula that was subsequently successfully repaired). In eight of these 10 cases the care was judged to be appropriate.

The average payment for a major temporary injury (category 4) was $45,431, with a range of $15,000 to $175,000. Eleven of the 21 patients received payment. Ten of 11 cases in this category resulted in payment of <$55,000. Only in three of the 11 cases was the care judged to be appropriate.

In category 5 (minor permanent injury) (nine cases) three payments of $29,999, $50,000, and $175,000 were made, for an average of $85,000. One of these cases met the standard of care.

Major permanent injuries (category 6) (12 cases) resulted in payment in five cases. The average was $112,440 and the range was $2200 to $250,000. Four of the five cases involved allegations of unnecessary hysterectomy. Two of the five met the standard of care. Two $250,000 cases were in this category, involving in each case a hysterectomy in a young woman.

In category 7 (grave injury) there was only one patient. This patient suffered a cerebrovascular accident postoperatively. Care was judged appropriate and no money was paid.

The five cases with death all received money (Table VI). The average payment was $127,000 with a range of $40,000 to $250,000. The standard of care was met in one of the five. The care in that case was judged appropriate both by the local society medical review audit committee and by the chairman of a respected teaching program in California. The case was settled for a $40,000 payment to the estate of a 33-year-old patient who suffered a series of seizures of undiagnosed cause on postoperative day 1 and died the next day.

All of the other four cases were judged to fall below the standard of care. The $250,000 settlement was made in the case of a 39-year-old obese woman who underwent a difficult hysterectomy and Marshall-Marchetti-Krantz procedure. She was noted to be anuric immediately postoperatively, but a substantial delay occurred before a diagnosis of bilateral ureteral ligation and severe intraabdominal hemorrhage. The patient also aspirated at the start of the second operation as the surgeon removed the dressings and sutures before intubation. She died shortly after completion of the second operation.

Table III. Standard of care and compensation summary

Standard of care	*% of Patients compensated*	*% of Patients not compensated*
Met	23	77
Not met	71	29

Table IV. Patient's age and compensation in lawsuits lost or settled

Age of patient (yr)	*Average compensation*	*Range of compensation*
<30	$101,600	$6,000-$250,000
30-49	$46,900	$1,000-$250,000

A $210,000 settlement was awarded to the estate of a 41-year-old woman who underwent vaginal hysterectomy and anterior and posterior colporrhaphy for treatment of urinary stress incontinence and uterine prolapse, followed immediately by an abdominoplasty performed by a plastic surgeon. Shortly after operation the patient went into shock. The gynecologist did not assess the patient until several hours after the initial telephone call from the hospital. On reoperation, the abdomen was filled with blood. A lacerated spleen of unknown cause was diagnosed; splenectomy was performed, and the patient did not recover. An additional $110,000 was paid on behalf of the plastic surgeon.

The fourth case resulting in death was settled for $75,000. The patient was a 55-year-old obese smoker with numerous medical problems who was a poor operative candidate. In 1983 she underwent total abdominal hysterectomy and bilateral salpingo-oophorectomy for treatment of carcinoma in situ of the cervix without a preoperative medical evaluation. The surgeon was a board-certified family physician. The patient suffered major blood loss at surgery, had a cardiac arrest on postoperative day 1, and died.

The final death occurred in a 58-year-old woman who underwent abdominal hysterectomy and a Marshall-Marchetti-Krantz procedure for treatment of stress incontinence. She weighed 292 pounds, and no preoperative medical evaluation was performed. The surgeon was a board-certified obstetrician-gynecologist. The assistant was an ophthalmologist who had never assisted on an abdominal operation. Anesthesia was induced by a family practitioner with no formal anesthesia training. The patient bled to death on the operating table. The case was settled for $60,000. No urologic evaluation had been performed in any of the patients operated on for treatment of urinary stress incontinence.

Payment to the patient also varied by the appropri-

Table V. Severity of injury, compensation, and standard of care summary

Severity of injury	*No. of patients compensated*	*Standard of care met*	*Average compensation*	*Range of compensation*
Emotional	0			
Insignificant	1	1	$125,000	
Minor-temporary	10	8 of 10	$11,386	$1,000-$29,999
Major-temporary	11	3 of 11	$45,931	$15,000-$175,000
Minor-permanent	3	1 of 3	$85,000	$29,999-$175,000
Major-permanent	4	2 of 5	$112,440	$2,200-$250,000
Grave	0			
Death	5	1 of 5	$127,000	$40,000-$250,000

Table VI. Cases resulting in death

Age (yr)	*Preoperative diagnosis*	*Operation performed*	*Complication*	*Amount of compensation*	*Cost to defend*	*Standard of care*	*Outcome*
33	Urinary stress incontinence	Vag. hyst. A&P repair	Seizures on postoperative day 1	$40,000	$23,209	Met	Settled
39	Urinary stress incontinence	TAH MMK	Bilat. ureteral ligation Hemorrhage Aspiration Obesity	$250,000	$45,000	Not met	Settled

Vag. hyst., Vaginal hysterectomy; *A&P repair,* anterior and posterior colporrhaphy; *TAH,* total abdominal hysterectomy; *MMK,* Marshall-Marchetti-Krantz procedure; *BSO,* bilateral salpingo-oophorectomy.

ateness of care. In those cases where care was judged appropriate and payment was made, the average payment was $26,657 with a range of $1000 to $175,000. When care was judged inappropriate and payment was made, the average was $82,982 with a range of $1866 to $250,000.

One can also look at payment by allegation or injury sustained (Table VII). Bowel injuries accounted for three settlements. The average was $36,500 with a range of $29,500 to $50,000. Of five postoperative bleeding cases, excluding the death, only one cost money. It was settled for $1866. The two cases involving retained sponges were settled for $1000 and $10,000, respectively. The cases of death have been discussed. The two largest categories are urinary injury and alleged unnecessary hysterectomy. Fifteen of 37 cases of urinary injury (37%) resulted in payment to the patient. The average payment was $36,500, the range from $6000 to $175,000. Ten of these 15 cases settled below the California reporting limit of $30,000.

If unnecessary hysterectomy was alleged, payment was made in seven of 15 cases (46.7%). The average payment in this category was $122,000, with a range of $2200 to $250,000. Only two cases settled for <$30,000.

A total of 29 of 87 lawsuits (33%) were resolved by the company with defense costs of <$1000. A total of 26 cases were dropped after a lawsuit had been filed at an average cost to the company of $632. Seventeen cases were dismissed at an average cost of $5469. The 32 cases that were settled cost an average of $16,400 to defend. The one arbitration case cost $12,459 to defend successfully. The 11 cases that were tried cost an average of $37,000. Norcal spent $2,809,139 to pay for settlement and jury award in the 34 lawsuits where the patients received money. $1,935,650 was spent by Norcal to defend the 87 cases.

Comment

A total of 17% of the cases were based on an allegation of unnecessary hysterectomy. Seven of these 15 cases resulted in payment to the patient (Table VIII). The amount of payment was related to the age of the patient. Two cases are illustrative.

A 21-year-old nulliparous woman underwent laparotomy for management of suspected appendicitis. The surgeon, a family practitioner, saw pus at operation and diagnosed pelvic inflammatory disease. There was no abscess formation. The surgeon did a total abdominal hysterectomy and bilateral salpingo-oophorectomy. No

Table VII. Payment by type of injury to patient

Injury	*No. of cases*	*No. paid*	*Average settlement*	*Range of settlement*
Urinary	37	15	$36,500	$6,000-$175,000

consent for this procedure was documented. A jury awarded the patient $250,000.

A 32-year-old nulliparous woman underwent exploratory laparoscopy because of pelvic pain. The board-certified obstetrician-gynecologist suspected endometriosis at laparoscopy and proceeded immediately to total abdominal hysterectomy and bilateral salpingo-oophorectomy. No consent for the hysterectomy had been documented. Only normal tissue was noted on the pathology report. The lawsuit was settled for $125,000.

In four of these seven cases operation was done because of pelvic pain. None had documentation of alternative therapies having been tried. Three of the seven had no documentation of informed consent. Four had only normal tissue noted on the pathology report. Of the total of 34 cases in which payment was made, three cases cost $250,000 and two of those were in the unnecessary hysterectomy category. Clearly, gynecologists who plan or anticipate hysterectomy, especially in a woman under age 30, must be mindful of alternative therapies and must be explicit about documentation of informed consent.

The hysterectomies that resulted in death were also educational. Four of the five were preventable. In each of the four, serious errors in judgment occurred. The two very obese patients (>250 pounds) who were operated on for management of urinary stress incontinence should have had better preoperative evaluations and other therapies tried until sufficient weight loss occurred to make the operation less risky. Significant delays in recognizing and treating immediate postoperative complications occurred in two patients. Three of the four were extremely obese. None of the four had an indication for hysterectomy for which an acceptable alternative was not available.

The issue of cost to the company to defend these lawsuits is also of interest. In a few cases it appeared that a suitable settlement to the patient at very little expense to the company was achieved. It is also clear, as anticipated, that it is much more expensive to try a case than settle it. An average of $37,000 was spent to try the cases as opposed to $16,100 to settle. The numbers are small, but in this study, surprisingly, it was cheaper to try a case and win than to lose (an average

of $24,530 vs $34,213). Perhaps in difficult cases additional monies are spent on expert witnesses or attorney's time. Finally, it would appear that few cases ultimately go to court. If they do, the outcome for the physician-defendant is good. In 9 of 11 trials, the defendant prevailed.

Of all hysterectomies done in the United States 65% are performed on women aged 30 to 49; 12% are performed on women under age 30.[3] In this study 65% of operations were indeed performed on women aged 30 to 49, but 22% were on women under age 30. One can conclude that the risk of lawsuit is substantial when a hysterectomy is performed on a patient under age 30. Again, this emphasizes the need for careful consideration before elective hysterectomy is recommended to a woman under 30.

As mentioned, there were eight cases in which the standard of care was not met, yet the patient received no payment. Five of these cases were dropped, two were dismissed, and one was tried and a defense verdict obtained. Five of the eight had no documentation of informed consent. Four of the eight involved urinary injuries that subsequently were successfully repaired. Seven of the eight occurred in rural areas of Northern California. Only in the one case that went to trial did the plaintiff's attorney make any attempt to prosecute the case.

In summary, the standard of care significantly influences the likelihood and amount of payment to the patient. If care was below standard, 71% of cases received payment. However, if the care was appropriate, 23% of cases still resulted in payment to the patient. Second, in 59 of 87 cases (67%), the standard of care was met and yet a lawsuit was filed and closed. Therefore the filing of a lawsuit does not imply substandard care.

It is increasingly clear that the current tort-based system does a poor job of separating bad outcomes where there is no breach in the standard of care from those cases where an error was clearly made. We must continue to search for a fairer way to compensate the injured patient.

Discussion

Dr. Theodore W. Loring, Eureka, California. Dr. Whitelaw has provided us with an overview of the professional liability problems that have been caused by hysterectomies. It is a timely article; while it is economic and not scientific in nature, I think that it is as important to our specialty as any of the scientific articles being presented at this meeting.

He has reviewed the liability claims experienced by physicians insured by the Norcal Mutual Insurance Company during the years 1975 to 1985. The vast majority of the involved physicians were board-certified obstetricians who were in practice in Northern California. During this time the company experienced 262 hysterectomy claims, but only 87 of the closed cases with gynecologic indications for hysterectomy were reviewed.

Dr. Whitelaw has provided us with a detailed analysis of the cases and the problems that developed to cause the litigation. He has reviewed the procedures used by Norcal in evaluating the cases before making a decision to settle or defend. In contrast to policy of the commercial companies, physician review and input play a great part in the final decisions made by physician-owned companies. The injury summary in the author's Table II reveals that urinary tract injuries produced 37% of the cases, and unnecessary hysterectomies, the next most frequent, resulted in 17.2% of litigation. He rightly points out that the indemnity and expense costs to the company vary because of many factors.

The high proportion of urinary tract injuries and unnecessary hysterectomies in the Norcal series, although surprising, seems to be a major factor in other companies. Private data provided me by a large physician-owned company tends to confirm the Norcal data. In their claims experience from 1975 to 1985, involving both abdominal and vaginal hysterectomies in a much larger series of 312 cases, urinary tract injuries caused approximately the same percentage of claims.

The Physician Insurers Association of America, the national organization representing 42 physician-owned companies, has started a cooperative data-sharing system in which most of the companies are participating. The study from 1985 to 1988 shows that the most frequent iatrogenic injury that occurred in 809 closed files involving hysterectomy was urinary tract injury (36.7% of the cases). Obviously the neurologically impared newborn engenders the most severe type of claim. However, hysterectomy claims represent a significant portion of the files. The average indemnity paid was $80,324 for abdominal hysterectomy and $66,894 for vaginal hysterectomy for an overall average indemnity of $77,818. In this series hysterectomy cases accounted for 9% of all obstetrics and gynecology claims.

While these facts are distressing, it is important to remember that, when there is no deviation from the accepted standard of care, the jury usually will render a verdict in favor of the defendant physician. A recent national study, done by the American Bar Foundation, reveals that the plantiff success rate for 1981 to 1985 for all civil jury verdicts was 58.4%; for medical malpractice jury verdicts, 28.0%; and for obstetrics and

gynecology jury verdicts, 10%. Plaintiff success verdicts tend to vary with the severity and permanency of the injury and to some degree with where the case occurs. From the same study, the plantiff success rate in obstetrics and gynecology cases in Los Angeles County was 37.5% while in San Francisco County it was 25%.

Professional liability, often inappropriately labeled *malpractice,* has bedeviled all physicians *regardless of their specialty* or *indeed their recognized competence.* It has been with us almost since Adam and Eve. In the original minutes of the formation of the Medical Society of Humboldt County (California), a small society, organized on February 20, 1886, there is a reference to malpractice. The minutes state: "The Society should on all occasions stand by any member who should be arraigned on such a charge unless the member's action was totally indefensible." It was also agreed that the organization would spare no efforts to discourage the levying of "blood money" by means of malpractice suits, and at the discretion of the majority of the total membership such patients might be denied future care from physician members. As early as July 1, 1909, the members of the Medical Society of California could become members of an Indemnity Defense Fund. The Medical Society of the State of New York was formed in 1806, and one finds references to medical malpractice even in its early publications.

It is generally stated that professional liability is much worse today than in the "good old days," especially on our specialty. No longer can anything less than a perfect result in patient care, be considered an act of God, as in the "good old days." Malpractice litigation has profoundly affected our professional lives and our checkbooks.

We are unhappy with the tort system as a means of handling this problem, but in reality there is no alternative on the horizon. The problem could be much worse. A study by the California Medical Association and the California Hospital Association suggests that 1 in 20 hospitalized patients experiences some medical error that could produce a potential compensatory injury. In the United States this could produce at least 1,715,000 claims but only about 10% of patients actually file claims.

Unfortunately maloccurrences and indeed malpractice will continue to occur, and there will always be a few unhappy patients as long as we practice medicine. Most of the physician-owned companies have instituted claims-prevention education programs for their insured, and to date this seems to be having a positive effect on this problem.

I compliment Dr. Whitelaw on his very detailed review of the hysterectomy-liability problem and have one question to ask him. What does he see as alternatives to the tort system?

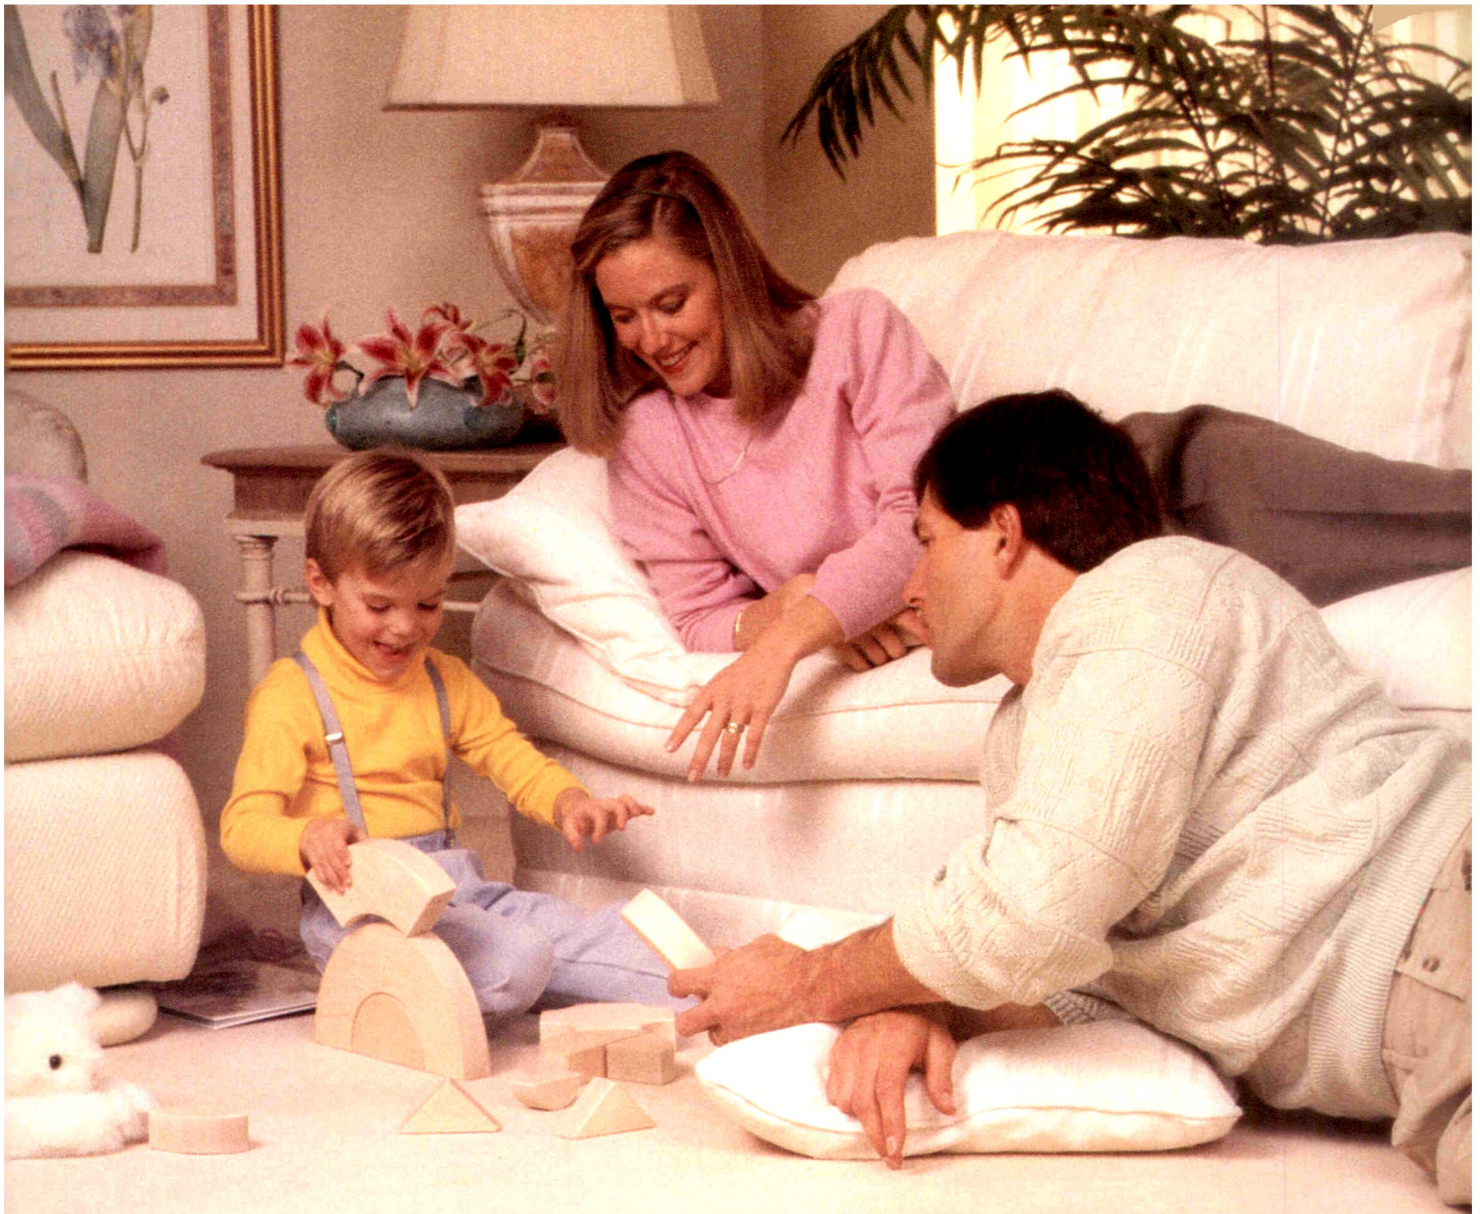
Dr. Keith Russell, Los Angeles, California. Dr. Whitelaw's article emphasizes several important points. However, a study of closed claims is deceiving in many ways because there are so many nonmedical factors that enter into the closing process—the skills of the attorneys, the position of the carriers, and the selection of juries, for instance. If you review closed claims retrospectively, you will find many in which the medical aspects are of less importance in the closing than these other factors. Dr. Whitelaw pointed this out by citing eight cases in which medical care was definitely below the standard and yet, for various reasons, no money was paid out. The medicolegal world is often entirely different from the world of medical practice. A leading attorney for the California Medical Association describes a malpractice trial as a drama in which we play roles. Review of closed claims points out only some of the factors that may enter into this courtroom drama.

We hear daily about high-risk obstetrics but seldom about high-risk gynecology. Dr. Whitelaw's report points out that three of the five deaths were associated with severe obesity. The obese patient is a high-risk gynecology patient, but many of our colleagues, I find, operate on such patients as "routine" cases. It is mandatory that for these cases we have adequate preoperative evaluation, skilled assistants, skilled anesthesiologists, and careful postoperative care including the use of pulsating thromboelastographic stockings and possibly the use of heparin. That the obese patient cannot be treated as an ordinary surgical case needs to be emphasized.

The medicolegal risk of hysterectomy is minor compared to the risk of failure to diagnose or properly manage diseases of the breast. In the national insurance registry of the Association of Doctor Owned Insurance Companies, breast cases far exceed other gynecologic cases.

Dr. Whitelaw, you mention reviews by medical review audit committees. At one time we thought the answer to some of our litigation problems was to have our peers review our cases and tell us how to defend them, yet in most medicolegal cases that mechanism either is not implemented at all or plays little role in the eventual outcome. I would like to know your feelings regarding medical review audit committees. I am part-time consultant for one privately owned and two doctor-owned insurance companies in Southern California. I find these so-called review committees have very little role when the attorneys begin to discuss the case.

Of the 87 closed cases, Dr. Whitelaw, how many were closed by jury action and how many were settled by the carriers or other parties? I suspect that something like 90% were settled and 10% decided by juries. It is encouraging that, of the cases involving obstetrician-gynecologists that have gone to a jury in California in the last 15 years, roughly 65% are found for the defense (the doctor or the hospital) and only 35% for the plaintiff. I believe that Dr. Whitelaw's figures will show that also. Doctors involved in a malpractice action often say "Well, I don't want to settle the case because that's an admission of malpractice. I don't feel that there was any malpractice." From a financial standpoint, however, it is often more economical for the physician's insurer to settle than it is to go to court, even though the physician has a two out of three chance of winning the case.



Dr. Whitelaw (Closing). Dr. Loring, I don't have an alternative to the court system. I firmly believe that there is a role for arbitration although I recognize that insurance companies don't like to hear this. In this study the one case that was arbitrated resulted in a defense verdict, but the plaintiff exercised her option to take it to court and the company paid her $7000 not to. Somehow we usually get to the issue of who has the best lawyer and who can do the best job of swaying the jury. I am not sure that I, anymore than anybody else, have an answer to that.

Dr. Russell, 11 of the 87 cases went to trial and nine of those resulted in a defense verdict. Medical review audit committees did play a role at one time, but usually the expectations for their effectiveness were not met. However, they did provide the defense attorneys with access to physicians with an unbiased view who are skilled in case review and at no cost to the company. For this article I used those reports that were available only for assessment of the standard of care. Your points on closed case review and the major problem of failure to diagnose are both very well taken.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the American Journal of Obstetrics and Gynecology

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the American Journal of Obstetrics and Gynecology from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

L O W D O S E

LO/OVRAL® 30 mcg

each tablet contains 0.3 mg norgestrel and 30 mcg ethinyl estradiol, Wyeth

Prescribe it with confidence

IN BRIEF:

Indications and Usage—LO/OVRAL* is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions:

1. Thombophlebitis or thromboembolic disorders.
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders.
3. Cerebral-vascular or coronary-artery disease.
4. Known or suspected carcinoma of the breast.
5. Known or suspected estrogen-dependent neoplasia.
6. Undiagnosed abnormal genital bleeding.
7. Known or suspected pregnancy (see Warning No. 5).
8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exits, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of the method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users.

If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40- to 49-years-old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polysystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with the use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind.

In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these pre-existing problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests.

As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related: nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

The efficacy of external cephalic version and its impact on the breech experience

Joseph W. Hanss, Jr., MD
Phoenix, Arizona

With the introduction of ultrasonography, tocolysis, and electronic fetal monitoring, external cephalic version is considered safer and is more frequently used for the management of breech presentation. A retrospective review of a level III obstetric unit for the year 1988 is reported. Three hundred fifty-seven breech births were recorded. One hundred twelve patients were seen for external cephalic version. Forty-seven patients (48.9%) were successfully converted from breech. The cesarean section rate of successful versus unsuccessful version was 17.2% and 77.5%, respectively, which demonstrates the effectiveness of the technique. The overall impact is small. Success measured as a vaginal cephalic delivery of a previously known breech presentation represented <0.5% of all deliveries and <10% of all breech deliveries at this institution during 1988. (Am J Obstet Gynecol 1990;162:1459-64.)

Key words: External cephalic version, breech presentation, reducing cesarean section rates

Breech presentation has always been a challenge to those physicians who are involved with the birthing process. A historical study of obstetric care for breech presentation reveals the following: Hippocrates was said to practice external cephalic version, but when all attempts failed, fetal destruction was carried out and a large number of enabling instruments were designed over the ensuing centuries.[1] Mauriceau, Smellie, Veit, and Braxton Hicks were but a few who began to understand the mechanism of breech delivery and to develop techniques of assisting and extracting the breech.[2] Piper added forceps to the aftercoming head.[3] Some, such as Potter, became so enamored with breech delivery that all of his infants were delivered by breech extraction, even with internal version if necessary. During the twentieth century, cesarean section became safer for mothers and its liberal use has nearly eliminated the fetal mortality associated with breech presentation.[4]

Our ethical dilemmas through the years have progressed through maternal mortality, fetal mortality, fetal morbidity, and currently, cesarean section rates. The science and philosophy of the above tend to be interpreted within the egocentric framework of the "art" and the "technology" of obstetrics.

Beginning in the late 1960s, neonatal life support technology advanced so rapidly that in less than 20 years the age of viability decreased from 35 to 25 weeks' gestation. The survival of very-low-birth-weight infants in today's neonatal intensive care units has nearly eliminated the heartrending decision as to when appropriate and safe operative intervention of pregnancy is reasonable.

Because the incidence of breech presentation is inversely related to the gestational age at birth,[5] and since the overwhelming evidence supports cesarean section as the delivery method of choice for the premature breech, it would follow that the number of infants born from the breech may increase as the age of viability continues to decrease and the number of cesarean sections will correspondingly increase. The obstetric delivery method of choice for the term breech is not as clearly defined.[6-8] Cesarean section today has significantly reduced neonatal mortality. However, neonatal morbidity with cesarean section and vaginal delivery seemingly are the same.[6]

This article addresses the following questions: (1) is external cephalic version near term effective? (2) is it safe? and, (3) in a large obstetric service, does it have any impact on the overall breech experience and cesarean section rate?

Material and methods

A retrospective review of a level III obstetric service in a community teaching hospital was completed for the year 1988. Attention focused on all patients scheduled for external cephalic versions, and all those with breech presentations at the time of delivery.

Our protocol provides that any candidate for external cephalic version be admitted to the labor suite to ensure the availability of emergency services. After appropriate informed consent and permit signatures, fetal monitors are applied and ultrasonographic evaluation is done to determine presentation, placental localization, and amniotic fluid volume. Ultrasono-

graphically directed manipulation of the breech under tocolysis with either intramuscular or intravenous terbutaline is followed by electronic fetal monitoring. Rh immune globulin is administered when indicated. With adequate reassurance of fetal well-being, the patient is usually discharged to continue prenatal care at home and to await the onset of labor.

A successful version is defined as a conversion from breech to cephalic presentation. The ultimate outcome of pregnancy in both groups, successful version and unsuccessful version, is evaluated and compared. All breeches, corrected breeches, and the overall cesarean section rates for 1988 are then related to cephalic version.

One hundred forty-eight patient appointments for external cephalic versions were scheduled during the year 1988 (Table I). One hundred twelve visits were recorded. Thirty-six patients failed to keep their appointments. Ultrasonographic screening revealed an additional 16 patients whose fetal presentation was cephalic. External cephalic version was therefore attempted on 96 patients.

Results

Forty-seven (48.9%) successful versions from breech to cephalic presentation were accomplished (Table II). Forty-nine (51.0%) attempts were unsuccessful. Subsequent follow-up (Table III) revealed that 38 (80.8%) of the patients with successful versions were delivered vaginally. Eight patients (17.0%) were delivered by cesarean section and one was lost to follow-up. One fetus reconverted to a single footling breech and was delivered by cesarean section. The most common indication for cesarean section was failure to descend in labor.

Forty-nine attempts at cephalic version were unsuccessful. Examination of this group showed that 38 (77.5%) were eventually delivered by cesarean section, and five (10.2%) were delivered vaginally, (three breech, two cephalic). One of the cephalic presentations followed a repeat and successful version. One spontaneously converted to a cephalic presentation. Four patients of this group were lost to follow-up. The common indication for cesarean section of this group was breech presentation. Sixteen patients admitted for external version were found to have a cephalic presentation. Follow-up of this group showed that 10 women were delivered vaginally, four by cesarean section, and one was lost to follow-up. All vaginal deliveries were cephalic presentations. Two of the cesarean sections were for breech presentation. Thirty-five patients failed to keep appointments for external version. Follow-up of this group was nearly impossible. Pregnancy outcome could be determined in only seven of those 35 patients. Two were delivered vaginally and five had cesarean sections.

There was no recorded morbidity associated with the version procedure within the study. Maternal or fetal hemorrhage, fetal injury, fetal distress, premature labor, or premature rupture of membranes were not observed.

In 1988, 6627 births were recorded in the index institution (Table IV). There were 908 (13.7%) primary cesarean sections and 539 (8.1%) repeat cesarean sections [total, 1447 (21.8%)]. Three hundred fifty-seven (5.4%) of all infants were born from a breech presentation. Of all breech presentations (357), 73 (20.4%) were delivered vaginally, 284 (79.5%) were delivered by cesarean section (231 (64.7%) primary, and 53 (14.8%) repeat cesarean sections).

It is customary in the literature to correct breech presentation statistics for intrauterine death, twins, and congenital anomalies. Table V lists by weight-specific category all infants born from a breech presentation excluded according to these criteria. Table VI shows that 36 (13.6%) corrected breech infants were delivered vaginally. Two hundred twenty-eight (86.3%) were delivered by cesarean section. Therefore, excluding those breeches associated with intrauterine death, multiple gestation, and congenital anomalies, the corrected number of breech deliveries was 264. Excluding prematurity, and thereby focusing on single healthy infants with birth weights greater than 2500 gm, there was a total of 150 term healthy breech infants. One hundred thirty-four (89.3%) of these were delivered by cesarean section and 16 (10.7%) were delivered vaginally.

In summary, of 6627 recorded births during 1988, 1447 (21.8%) were delivered by cesarean section. After

Numbers in parentheses represent the percentage of all presentations; numbers in brackets represent the percentage of all breech presentations.

correction for prematurity, fetal death, multiple gestation, and congenital anomalies, 150 term infants were delivered from the breech presentation. One hundred thirty-four (89.3%) were delivered by cesarean section. Sixteen (10.7%) were delivered vaginally. In addition to the above breech presentations, 47 successful cephalic versions were accomplished. If it is assumed that the cesarean section rate for these cases is 89.3%, if the infants had remained in the breech presentation, an additional 41 cesarean sections would have been required to deliver all breech cases for the year 1988. The overall cesarean section number would rise from 1447 (21.8%) to 1488 (22.4%), a difference of 0.6%.

Comment

The management of breech presentation and delivery in the United States has encompassed scientific, legal, and ethical consideration of both mothers and infants. Within the lifetimes of many of us, maternal risk from cesarean section has been dramatically reduced.

It is my opinion that too many of our recently trained specialists consider cesarean section a safer and better method of breech delivery for both mother and baby than use of forceps, or any manual manipulation of the fetus. Without exception, no other obstetric variation but the breech presentation has provided us the opportunity to abandon all scientific information, and to plunge forthwith into operative intervention. This is substantiated in this review by the following observations. Almost 90% of all term breech presentations were delivered by cesarean section, and there was an alarming lack of documentation concerning the classification of the breech presentation. The predominant indication for operative intervention was "breech in labor."

Table V. Number of breech infants by weight-specific categories excluded for intrauterine death, twins, and congenital anomalies

sional and lay literature to resurrect the technique of external cephalic version as a means of reducing our increasing and alarming cesarean section rate. Resurrection of the technique itself is not new. In another age, according to Edgar in 1904,[1] "Before the sixteenth century, it (cephalic version) was practically the only version used, but at that time podalic version was introduced and because of the ease of its performance, became very popular, and on this account, cephalic version was almost abandoned, although more recently revived by some obstetricians." External cephalic version became a well-recognized procedure after the publication of Hubert and Pinard in the 1800s,[2] it was found to produce a zero neonatal mortality by Mehta in 1944,[4] was advocated by Macarther in 1964,[9] and was said to have decreasing value by Bradley-Watson in 1975.[10] Ylikorkala and Hartikainen-Sorri[11] first reported the use of ultrasonography in conjunction with external version, and finally tocolysis became a factor that was to further reduce the complications and increase the success of cephalic version.[12-14]

In this review, I was surprised, as were Flanagan et al. in their presentation to this society in 1987,[15] to discover that our current success for external cephalic version was <50%. This success rate, despite ultrasonography and tocolysis, is little different than that reported by both Williams[2] and Edgar[1] at the turn of the century. However, the overwhelming difference in the rate of cesarean section versus vaginal delivery among successful versus unsuccessful versions is striking. The study demonstrates that in a community-based level III teaching obstetric service, 38 women who underwent cephalic version near term were delivered vaginally, thereby avoiding maternal risk, cost, and neonatal morbidity associated with cesarean section for breech presentation.

The technique of version is apparently safe. At no time in the 96 attempted external versions was a major maternal or fetal complication recorded.

Finally, is there a major impact on the 1988 cesarean section rate by the use of external cephalic versions? Routine cesarean section for breech presentation was initially recommended in 1959[7] and became common in the United States in the mid-1970s, presumably as the legal risk of vaginal delivery of a breech presentation increased. This review demonstrated an almost 90% cesarean section rate for corrected term breech delivery. With this approach to the treatment of the breech, any attempt to prevent a breech presentation is valuable. Successful cephalic version allowed 38 women to be delivered vaginally and thereby avoid cesarean section. On a service where 6664 obstetric deliveries were recorded, 1447 cesarean sections were performed. Sixteen singleton term breeches were permitted to be delivered vaginally. External cephalic version reduced the potential cesarean section rate by 0.6%. The resurrection of an ancient technique for a far different reason than during the days of Hippocrates remains valid. To consider cephalic version a solution to our current problem of high cesarean section rates is not substantiated and we must seek other studies to determine methods that might significantly lower the cesarean section rate in the United States.

Discussion

DR. DAVID PENT, Phoenix, Arizona. There has been considerable interest, both within our profession and in the media, concerning the high cesarean section rate and how to lower it. Dr. Brooks Ranney, in his 1973 paper, "The Gentle Art of External Cephalic Version," which detailed his experience with 860 attempted cephalic versions, stated that "conservatively estimated in various ways, the probable cesarean section rate for this entire group, without the use of version, would have been between 9% and 10%," instead of the 7.2% rate he reported.[1] As recently as last year, the "Update" audio cassette tapes,[2] sponsored by the American College of Obstetricians and Gynecologists, in an issue on cesarean sections, noted that the rate could be reduced by an increase in vaginal births after cesarean section and by the more widespread use of external cephalic version.

Dr. Hanss' paper beautifully illustrates that in his hospital the impact of external version on the section rate is disappointingly small. Even his figures, I believe, are optimistic. Very simply, we do not know how many of the fetuses who were successfully turned by external version would have turned spontaneously before the onset of labor. The patients in this series were at 36 weeks or later in gestation. Dr. Raymond Jennett graciously provided me a computer printout of his statistics from St. Joseph's Hospital in Phoenix. At 36 weeks' gestation 8.168% of the deliveries were breech, and at 40 weeks' this figure was 4.403%. This represents a spontaneous 46% change, remarkably similar to Dr. Hanss' reported 49% successful version rate. Obviously there are errors inherent in the comparison, including the fact that some of the version patients were past the thirty-sixth week, and also that the percentage of breeches delivered at any gestational age is greater than the percentage of fetuses in the breech position, since the latter position is thought to be conducive to premature labor. Similarly, it is unfortunate that more data could not be obtained regarding the patients who failed to keep their appointments for external version. Of the seven patients for whom we have data, two converted spontaneously. That represents 29%, but of course the numbers are too small for statistical significance.

Brooks Ranney notes that attitudes concerning external cephalic version may be summarized by quoting J. L. Macarthur, who wrote, "There are those who enthusiastically recommend it, others who violently oppose it and still others who express a rather elegant distaste for it."[3] Indeed as one reviews the literature, one sees dogmatic statements made both for and against version, with an extreme paucity of any type of data to support the conclusions. What is needed, now that we have entered the era of ultrasonography, fetal monitoring, and tocolysis, is data to relate how many fetuses are breech presentations at any given time in gestation and what is their "natural history." This could be ascertained by ultrasonographic examination, which would be able to define the exact presentation, because it is thought that frank breeches are more difficult to turn, with the extended legs acting as splints. Therefore there may be value in identifying a subgroup of breech presentation for whom version may or may not be of value. It also would be profitable to compare hospitals, or groups of physicians, who do versions with those who do not. This has been reported in the past, and claims were made that hospitals that do not do versions had lower morbidity and mortality rates, but the exact figures are hard to determine and do not reflect the techniques currently being used.

Finally, we need more data to evaluate cost effectiveness. At Dr. Hanss' hospital, the hospital charge for a vaginal delivery ranges from $1800 to $2600. The hospital charge for an external cephalic version is $900, one third to one half the cost of a vaginal delivery. At that price we will have difficulty teaching versions to residents, so that they can develop the important necessary experience.

I have two questions for Dr. Hanss. First, he mentions one unsuccessful version that was converted on a second attempt. Were there any other patients who underwent more than one attempt at cephalic version? Dr. Ranney probably holds the record in this regard, finally turning a baby on his eighth attempt and raising the question as to who was more stubborn—the fetus or the physician. Second, what were the contraindications for external cephalic version in these cases?

DR. HANSS (Closing). Dr. Pent, there were only two repeat versions attempted. There is no effort on our

service to select patients based on the volume of amniotic fluid nor on the type of breech. All women who were seen with breech presentations were accepted for an attempt at version. Perhaps that lack of selection lowered the percentage of success. The earlier that version is attempted—at 28, 30, or 32 weeks—the greater the success rate. Not only are there more breech cases at 30 weeks, but at this gestational age the majority would spontaneously convert to cephalic presentation. The only contraindications to version in this study were ruptured membranes or loss of heart rate variability on the monitor.

Green et al.[1] pointed out in 1982 that the perinatal morbidity associated with vaginal delivery of a breech presentation is similar to that with cesarean section. In my review, I found a number of breech infants born by cesarean section who had low Apgar scores. I did not count them so I do not have a definite answer. We can certainly eliminate the destructive instruments that obstetricians have known in the past, but we still must teach our residents the mechanism of breech delivery and some techniques for breech delivery including the Mauriceau-Smellie-Veit, the modified Prague maneuver, and the use of Piper forceps. Delivering a breech infant through an abdominal wall incision is very little different in terms of the mechanisms from delivering a breech through the vaginal canal. Today, many of our residents are deficient in the knowledge and skill necessary to safely extract a breech from the uterus, even through a lower uterine incision.

Diagnostic and therapeutic curettage in gestational trophoblastic disease

John B. Schlaerth, MD, C. Paul Morrow, MD, and Maria Rodriguez, RN
Los Angeles, California

From June 1976 through June 1989, 37 nonconsecutive patients underwent uterine curettage during the course of their gestational trophoblastic disease. In 22 patients (59%) trophoblastic tissue was obtained. Three (8.1%) patients sustained a uterine perforation during the procedure. In six patients curettage was performed for bleeding. There were six patients curetted during assessment for metastatic trophoblastic disease. Twenty-eight patients underwent curettage for the presumed diagnosis of nonmetastatic gestational trophoblastic disease. In retrospect, four of these women (14.3%) had insufficient criteria for the diagnosis of gestational trophoblastic disease. Of the remaining 23 patients, four (17.4%) went into clinical remission without further treatment. Ten patients (43.5%) had a transitory decline in serum β-human chorionic gonadotropin levels that subsequently rose or plateaued. Six patients (26.1%) showed no effect from the curettage on their serum β-human chorionic gonadotropin trend during a short period of observation. Three patients (13.0%) with nonmetastatic gestational trophoblastic disease were not observed for a possible therapeutic effect after curettage. Thus, in only 4/20 (20%) women with nonmetastatic trophoblastic disease was a therapeutic effect from curettage shown. (AM J OBSTET GYNECOL 1990;162:1465-71.)

Key words: Curettage, gestational trophoblastic disease, effectiveness, risks

Uterine curettage has traditionally been regarded as important for diagnostic and therapeutic reasons in the assessment of women with gestational trophoblastic disease.[1-3] In fact repeated curettages have been a common practice.[4] Yet there has been little critical evaluation of curettage in this setting.[4-6] For this reason a retrospective review of the uterine curettages performed in women presumed to have gestational trophoblastic disease at our institution was undertaken. The purpose of this study is to examine the advantages and disadvantages of curettage in women with gestational trophoblastic disease.

Material and methods

The medical records of all patients who underwent uterine curettage during follow-up for hydatidiform mole or suspected gestational trophoblastic disease at Los Angeles County–University of Southern California Women's Hospital were reviewed. Twenty women were curetted during the 46-month period from June 1976 through March 1980. Two of these women had a gestational choriocarcinoma not preceded by a hydatidiform mole. Interest in curettage for such patients waned during the next 7 years. Another 17 women underwent curettage during follow-up for hydatidiform mole in the 20-month period from November 1987 through June 1989. During these two time periods a repeat curettage was performed during the follow-up for hydatidiform mole if (1) β-human chorionic gonadotropin serum (β-hCG) levels plateaued or rose or (2) excessive uterine bleeding occurred.

The clinical records were reviewed for initial management of the hydatidiform mole, the presence of bleeding, the size of the uterus, the trend of serum β-hCG levels before the curettage, the level of serum β-

hCG at the curettage, and for evidence of metastasis. Further, the quantity of the curettage specimen and the histologic descriptions were analyzed.

A uterus was considered enlarged if a sounding exceded 10 cm or the estimate of size was >8 weeks' gestational size. Persistent gestational trophoblastic disease was diagnosed by a rise or plateau in serum β-hCG levels or by the appearance of metastasis. A rising trend in serum β-hCG levels was defined as doubling in value over a 2-week period. A plateau in hCG levels was generally considered to be present when no decrease in serum β-hCG level was apparent during 3 weeks of observation and any increase was insufficient to qualify as a rising trend. Assessment for metastasis included history and physical examination, liver function tests, chest roentgenogram, pelvic ultrasonographic examination, and computerized tomography of the chest, abdomen, brain and pelvis. Earlier patients underwent radioisotope scans of the brain and liver and pelvic angiography. The uterine curettage specimen was considered positive if a histologic diagnosis of a gestational trophoblastic disease or trophoblastic cells were detected, otherwise it was considered negative for diagnostic purposes.

Last, the details in management and clinical outcome were determined for all patients.

Results

General observations. The yield from the curettages were analyzed for the 24 women with nonmetastatic

trophoblastic disease (Table I). Fifteen of 24 (62.5%) of those patients exhibited some aspect of trophoblastic histology.

The uterine sizes were analyzed in reference to the diagnostic yield on the curettages. The curettings from eight of 12 (66.7%) large uteri contained trophoblastic elements. The curettings from 25 normal-sized uteri showed trophoblastic tissue in 13 (52%).

Bleeding. Six patients underwent uterine curettage because of significant bleeding (Table II). Four of these women were clinically considered to have retention of molar tissue after evacuation. Two of these patients were evacuated at our institution, one (P. C.) by suction and sharp curettage to complete spontaneous abortion of the hydatidiform mole and the other (L. M.) underwent elective suction and sharp curettage for an intact hydatidiform mole. No details of primary management are known for the other two women (M. H., D. D.). One woman with metastatic postmolar trophoblastic disease and one woman with postabortal choriocarcinoma also underwent curettage. It should be noted that this last patient sustained a uterine perforation that led to laparotomy and hysterectomy.

Persistent trophoblastic disease

Metastatic. Six patients underwent uterine curettage as part of their assessment for metastatic trophoblastic disease (Table III). The preceding gestation in five patients was a hydatidiform mole and a tubal pregnancy in one (G. A.). One patient (A. P.) with metastasis was first seen with bleeding and is included under both groups of patients.

Nonmetastatic. A total of 28 women underwent uterine curettage for presumed nonmetastatic postmolar trophoblastic disease on the basis of the trend of serum hCG levels. Two women with serum hCG trends suggesting postmolar trophoblastic disease also were first seen with bleeding and are included in Table II.

Despite a trend of serum β-hCG levels to substantiate the diagnosis of nonmetastatic postmolar trophoblastic disease, four patients had a significant drop in β-hCG level in the serum specimen drawn immediately before curettage (Table IV). Therefore, in retrospect the di-

agnosis of postmolar trophoblastic disease at the curettage could not be sustained. The diagnostic and therapeutic effects of these curettages are also questionable. However, one patient (E. C.) did have an invasive mole. Another patient (P. C.) is also included among those curetted for bleeding in Table I.

After curettage four patients went into complete remission without further treatment. There was no clinical suspicion noted that incomplete evacuation of the hydatidiform mole had occurred in these patients (Table V).

Ten patients had a decline in serum β-hCG values after curettage that was not sustained (Table VI). All these women subsequently had a serum β-hCG trend again indicating postmolar trophoblastic disease. All were successfully treated to remission with chemotherapy.

Six patients underwent curettage at the time of diagnosis of nonmetastatic gestational trophoblastic disease and showed no effect from this procedure on their disease as evidenced by a continuous plateau or rise in serum β-hCG levels during a period of observation afterward (Table VII). All these women were treated to successful remission with chemotherapy.

Four women with nonmetastatic trophoblastic disease had no postcurettage follow-up, which rendered them unevaluable for therapeutic effect from this procedure (Table VIII). One patient (P. F.) included here was also considered among the patients who were first seen with bleeding (Table II).

Comment

The curettages done for bleeding were not elective procedures and, as mentioned previously, four of these clinical situations were considered incomplete molar evacuations. But the presence of bleeding, the declining trend in serum β-hCG levels, molar tissue in 2/4 patients, and spontaneous remission after curettage fit

well with the concept of incomplete abortion as opposed to nonmetastatic postmolar trophoblastic disease. Two of these women had their initial evacuation at our institution. During the time periods of this study 140 patients received initial management of their molar pregnancy at Women's Hospital for a 2/140 (1.4%) incomplete evacuation rate.

In this series 21 of 37 women (56.8%) had curettages that revealed trophoblastic tissue. This experience is similar to the 46% and the 70% positive curettage rate reported in the two series by Berkowitz.[5, 6] Only nine (24.3%) women had a sufficient curettage specimen to allow a histologic diagnosis (eight hydatidiform moles and one choriocarcinoma). Nine women (24.3%) had trophoblastic tissue that, although insufficient in amount for histologic diagnosis would still allow analysis for prognostic features such as those described by Hertig[7] and Deligdisch.[8] Inasmuch as all patients who were not lost to follow-up in this series had remission of their disease with curettage, chemotherapy, hysterectomy, or a combination of these modalities, it is difficult to make a statement with regard to the importance of histologic diagnosis in clinical management.

Berkowitz[5] found that one course of chemotherapy with methotrexate and citrovorum factor was definitive therapy for 95% of trophoblastic disease patients who had no trophoblastic tissue in the curettage specimen, whereas 59% of women with trophoblastic tissue in their curettages required more than one course of therapy for clinical remission. It has been the practice at our institution to treat such women with weekly or biweekly courses of chemotherapy until one course has been given after a normal serum β-hCG level. This practice and the fact that several different chemotherapy regimens have been used in these women does not allow comparison on this point with the Berkowitz[5] series.

With the use of a serum β-hCG level of 50,000 mIU/ml Berkowitz[5] found a rough correlation with trophoblastic tissue in the curettage specimen and multiple courses of chemotherapy. However, in this present series (Table I) there was no apparent correlation between trophoblastic tissue in the curettings and serum β-hCG levels in patients with nonmetastatic trophoblastic disease. Therefore as a predictor of response, serum β-hCG levels seem more applicable clinically than diagnostic curettage results.

In our small experience with uterine curettage in metastatic gestational trophoblastic disease no benefit of curettage on an elective basis could be shown.

It is likely that the tradition for repeated curettages is based on older experiences with patients, such as those in Table V, in whom a convincing therapeutic effect was apparent after a plateau or rise in serum β-hCG levels. The analysis in this report did not disclose how these four patients differed from those patients whose nonmetastatic trophoblastic disease persisted after curettage (Table IX) other than that all their cu-

rettages were positive for trophoblastic tissue versus a 9/16 (56.25%) positive rate for the others. It is probable that most or all their trophoblastic disease was located in the superficial myometrium and the endometrium, both within reach of the curette.[1] In this regard diagnostic imaging techniques could prove helpful in the selection of optimal candidates for therapeutic curettage. Berkowitz[5] has reported that ultrasonography can be helpful in the prediction of a positive curettage 73.9% (17/23) of the time.

The intriguing observation that curettage may be definitive therapy in 20% (4/20) of patients with nonmetastatic trophoblastic disease must be tempered by the fact that all three patients (8.1%) who sustained a uterine perforation required laparotomy and two underwent hysterectomy. These three curettages were performed by third-year resident physicians with staff physicians in attendance. It is well documented that myometrial invasion, perforation, and hemoperitoneum can all occur spontaneously with trophoblastic tumors. This process renders elective curettage for postmolar gestational trophoblastic disease a procedure with some risk to fertility. This is of particular concern because most of these women are young with a current interest in having children.

In view of these facts, unless a group to benefit therapeutically from curettage can be clearly identified, there does not appear to be a significant place for elective curettage in women with postmolar gestational trophoblastic disease.

Discussion

Dr. Michael R. Smith, Seattle, Washington. Drs. Schlaerth and Morrow have reviewed for us the Los Angeles County Hospital experience with pretreatment curettage in the management of gestational trophoblastic neoplasia over the past 13 years. The purpose of their review was to assess the value of this traditional modality.

The data base consists of 37 patient records that detail curettage procedures in the course of gestational trophoblastic neoplasia evaluation. Six were done for bleeding, six for evaluation of metastatic disease, and 27 for assessment of nonmetastatic disease. Of the six done for bleeding, four were because of clinically obvious retained products after molar evacuation. In each case, bleeding was controlled and spontaneous remission ensued. In the fifth case, bleeding was controlled, but metastatic disease prompted chemotherapy. In the sixth case, uterine perforation prompted hysterectomy before chemotherapy.

No benefit, therapeutic or prognostic, was achieved in the five instances in which curettage was performed as part of the workup of metastatic gestational trophoblastic neoplasia.

Four of 27 who underwent curettage during evaluation of nonmetastatic gestational trophoblastic neoplasia required no further treatment. No therapeutic or prognostic benefit was noted in the remaining 23, and one required hysterectomy for uterine perforation.

Nine of 37 (24.3%) benefitted either through control of bleeding or eradication of disease. Two of 37 (5.4%) required hysterectomy for control of bleeding associated with postcurettage uterine perforation. Twenty-six of 37 (70.3%) derived no benefit whatsoever. All were ultimately cured of their disease.

The authors conclude that there is no clear indication for uterine curettage in the management of postmolar gestational trophoblastic neoplasia, except in the bleeding patient with evidence of retained tumor.

One must reconcile this advice with the recommendations of our colleagues in gynecologic pathology who, although not always in agreement with one another with regard to interpretation of an individual case, do find that the morphologic criteria found in the 60% or so of positive curettage specimens provide useful prognostic information.

Similarly, one must reconcile this advice with the recommendations of experienced clinicians who find that debulking of nonmetastatic gestational trophoblastic neoplasia by curettage may eliminate the need for chemotherapy in some patients and reduce the total number of treatment courses in others.

We are aided in our reconciliation by the abundance of data worldwide that show that the extraordinary specificity and sensitivity of the radioimmunoassay for the β-hCG far exceeds that of microscopic histopathology, immunochemistry, and diagnostic imaging in establishing both the diagnosis of gestational tropho-

blastic neoplasia and its response to treatment at no patient risk.

It is similarly abundantly clear that the success of systemic chemotherapy guided by serial β-hCG levels far exceeds that of surgical extirpation alone with comparable, or perhaps less, patient risk. Chemotherapy is clearly the gold standard, with surgery assuming an adjuvant role for resection of chemotherapy-resistent metastases or for elective hysterectomy in the patient with no interest in subsequent fertility.

The day before I received this manuscript, as if on cue a young woman 5 months after evacuation of a mole was referred to me. She had undergone two postevacuation curettage procedures before referral because of plateauing and subsequent elevation of her β-hCG titers even though her initial evacuation was thought to be complete and the first curettage was negative. She has since responded completely to three courses of methotrexate—two given while her titer was elevated and the final given after her titer returned to normal.

In 1981, Drs. Schlaerth and Morrow[1] helped us better understand the β-hCG regression curve, and today it is the role of uterine curettage in this disease. I look forward to their continued contribution to our understanding of this disease.

I have but one question for Dr. Schlaerth. If confronted with heavy bleeding in a young patient with postmolar gestational trophoblastic neoplasia and a normal sonogram or magnetic resonance imaging (MRI), how would you proceed?

REFERENCES

1. Schlaerth SB, Morrow CP, Kletsky OA, et al. Prognostic characteristic of the serum radioimmunoassay beta subunit human chorionic gonadotropin titer regression curve following molar pregnancy. Obstet Gynecol 1981;58:478.

Dr. Hisham K. Tamimi, Seattle, Washington. We have used intraoperative ultrasonography after the evacuation of 20 molar pregnancies in the past 5 years. The only patient who required chemotherapy was one with lung metastasis. I welcome your comments about the potential for this technique to minimize the need of repeat curettage and even to reduce the need for chemotherapy.

Dr. Joseph Oliver, Pasadena, California. When do you allow these patients to become pregnant again? Did amenorrhea or Asherman's syndrome develop in any of your patients because of curettage?

Dr. Schlaerth (Closing). Dr. Smith asked what I would do about a patient with heavy bleeding from postmolar gestational trophoblastic disease if she had a sonogram and MRI that revealed nothing suspicious. In one such patient, we did a curettage and the sonogram turned out to be a false-negative one, as it is in this setting from time to time. I have little information about the MRI in this setting. It takes a rather long time to do an MRI, and heavy bleeding may not allow that. The bottom line here is that the clinical situation would dictate what I would do. With heavy bleeding, my first response would be curettage.

Dr. Tamimi, your question about intraoperative ultrasonography is part of a larger question of the role played by imaging and endoscopy in the identification of patients who might be cured with curettage alone. We continue to search for solutions to the dilemmas our study has shown and imaging techniques may be the answer.

Dr. Oliver, by and large, for patients with nonmetastatic disease, we ask for a 1-year interval before they become pregnant again. I am not aware of any of our patients in whom Asherman's syndrome developed subsequent to curettage. However, our long-term follow-up, as I am sure you realize, is poor.

Prenatal diagnosis of intracerebellar hemorrhage: Case report

Raymond J. Jennett, MD,[a] William J. R. Daily, MD,[a] Theodore J. Tarby, MD,[b] and Kim H. Manwaring, MD[b]

Phoenix, Arizona

Evidence continues to accumulate that neurologic damage can occur during the antenatal period, unrelated to intrapartum events. We report a case in which intracerebellar hemorrhage was diagnosed by antepartum ultrasonographic examination. Correlation of fetal heart rate patterns, Apgar scores with neonatal course, and neuropathologic findings are presented. Medicolegal implications are discussed. (Am J Obstet Gynecol 1990;162:1472-5.)

Key words: Intracranial hemorrhage, intracerebellar hemorrhage, medicolegal implications

The availability of increasingly sophisticated imaging techniques has made it possible to diagnose hemorrhage and other intracranial lesions in the live infant before birth. This not only helps to support clinical decisions but allows comparison of fetal heart rate patterns, blood gas values, Apgar scores, and neonatal course with documented incidents of perinatal asphyxia in otherwise normal infants before an asphyxial event.

Case report

A 33-year-old woman was referred to the outpatient clinic at 35 weeks' gestation. The referring physician reported that the only unusual event before that time had been a hospital admission for suspected premature labor associated with a mild urinary tract infection. The patient had smoked more than a package of cigarettes a day throughout the pregnancy. No history of drug usage was obtained. Pertinent family history included her father and brother. Her father had incurred a stroke at age 32 followed by 7 years of coma before death. Her brother had a nonfatal myocardial infarction in his early 30s.

Two days after her initial clinic visit she reported a decrease in fetal movement. A nonstress test performed later that day was deemed to be equivocal and a contraction stress test was ordered. An oxytocin infusion was begun at a rate of 0.5 mU/min and gradually increased. Contractions began at a rate of 2.0 mU/min and were associated with persistent late decelerations from the start (Fig. 1). The oxytocin infusion was stopped and an ultrasonographic examination was performed. Fetal measurements were consistent with the menstrual gestational age of 35 weeks. Amniotic fluid volume was within acceptable limits. Of particular note was a large region of abnormal echogenicity involving the posterior fossa (cerebellum) and thalamus (Fig. 2).

Cesarean section was performed with the patient under epidural anesthesia. The amniotic fluid was clear

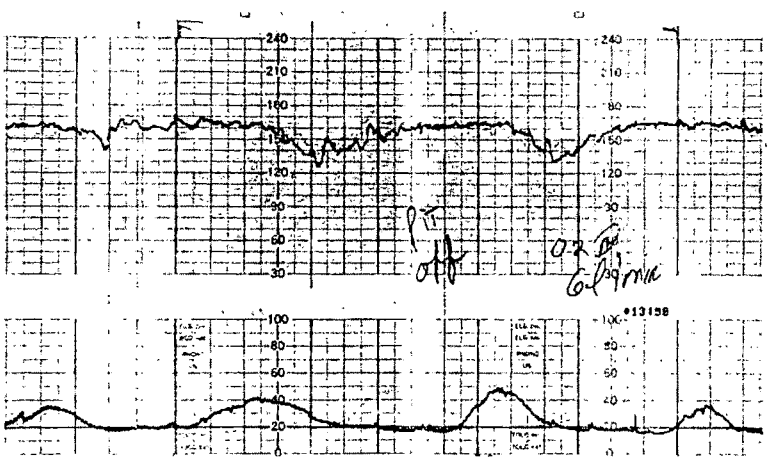

Fig. 1. Decelerations associated with oxytocin-induced contractions.

and there was no evidence of cord entanglement. The male infant who weighed 2693 gm and had a head circumference of 34.8 cm was described as pink with cyanotic extremities. He was limp and without reflex irritability or respiratory effort. Heart rate was less than 100 beats/min, resulting in a 1-minute Apgar score of 2. Cord blood gases were reported as pH 7.33 and pH 7.37 for arterial and venous blood, respectively. He was immediately intubated and given supported ventilation. His condition at 5 minutes was unchanged, resulting in an Apgar score of 2. Gasping respirations began at 65 minutes of age. Neither reflex nor spontaneous activity was present until 75 minutes of age when gradual spasmodic movements of the right arm and leg began, progressing rapidly to tonic-clonic seizure activity.

Cranial ultrasonographic scan showed massive hydrocephalus and a large echogenic structure in the right temporal lobe and atrium, spreading medially into the vicinity of the upper brain stem. Xenon-enhanced computed tomography showed evidence of hemorrhage in the left cerebellar hemisphere and thalamus. There was also hemorrhage in both ventricles.

A pulsed lumbar cysternostomy and right frontal external ventricular drain placement were done during the first day of life. Despite supportive treatment, the infant alternated between episodes of ventricular tachycardia and profound bradycardia. He had progressive acidosis, hyperchloremia and anuria, and died at age 46 hours. Pertinent autopsy findings were paraventricular leukomalacia with intraventricular, intracerebellar, and subarachnoid hemorrhage. No arteriovenous malformation was noted.

Fig. 2. Antenatal ultrasonographic scan of fetal head shows large thalamic and posterior fossa echogenic mass.

Comment

Although the cause of the massive cerebellar hemorrhage must remain speculative, certain observations are pertinent. Hemorrhage occurred in a fetus with adequate placental support as evidenced by a birth weight that was concordant with his gestational age and cord blood gases within a normal range. The latter observation is also supported by his pink color at birth, which is inconsistent with hypoxia just before the birth. This underscores the ambiguities of the Apgar score, which is comprised of diverse elements. A low Apgar score is widely considered synonymous with perinatal asphyxia, a concept that is formalized by the ICD-9 coding scheme.[1]

"Fetal distress" is a term with equally universal usage and similarly arbitrary definition. Certainly a fetus who has had a massive cerebellar hemorrhage is in "distress" in the most meaningful sense of the term. However, to rigidly equate fetal heart decelerations that occur in conjunction with contractions with placental insufficiency and fetal hypoxia is questionable because it ignores the possibility that an intracranial pathologic condition may result in increased sensitivity to repeated head compression manifested by similar decelerations. The value of obtaining cord blood gas determinations in such instances is suggested, as well as the use of cranial ultrasonographic scan or other imaging techniques in selected cases.

Finally, given the tremendous medicolegal problems arising from antenatal and perinatal brain damage, consideration should be given to the continued reporting of cases in which such damage is diagnosed prenatally. This is particularly the case for lesions commonly interpreted as occurring during birth and being traumatic in origin, as is cerebellar hemorrhage.[2]

We recognize our deceased colleague, Charles M. Hohler, MD, who performed the prenatal examinations.

Discussion

DR. JULIAN T. PARER, San Francisco, California. The authors have presented a well-documented case of fetal intracranial hemorrhage that occurred at about 35 weeks' gestation, before the onset of labor, in an infant born subsequently by cesarean section.

I would like to discuss this article from two points of view: first, the individual case, and second, the broader implications, such as incidence.

The cause of this intracerebellar hemorrhage is not clearly evident. Possibilities include trauma, asphyxia, infection, and congenital defects, such as vascular anomaly or blood dyscrasia.

There is not evidence for trauma but this may not rule it out. An intriguing report from New Zealand has suggested that trauma may not have to be particularly severe because there is a substantial increase in intracranial hemorrhages in Pacific Islanders among whom abdominal massage late in pregnancy is an established custom.[1]

The site of the lesion does not support asphyxia as a cause. Conversely, there is evidence from the mother's assessment of decreased fetal movement for several days before intervention. This could conceivably have indicated an episode of severe asphyxia, which resulted in the hemorrhage, and then resolved sufficiently to result in normal umbilical cord pH at birth. The role of the late decelerations is puzzling. Although the presence of late decelerations at the time of a contraction stress test does not preclude the subsequent birth of an infant with normal blood gas levels, it does suggest that resting uterine blood flow (without uterine contractions) is just adequate to ensure fetal oxygenation.

We are not given information regarding the ruling out of infection in this case, but perhaps Dr. Jennett can tell us if such data are available. The exact role of infection in such intracranial bleeding as presented here is not well established. However, in a series of 25 autopsy reports from near term stillbirths, all with intracranial hemorrhage or gliosis, Sims et al.[2] found evidence of infection in 36% of cases.

Congenital conditions explaining this case are lacking. A tantalizing aspect of the patient's family history is in her father's and sibling's early death and morbidity, respectively, in their 30s of cardiovascular causes. Another aspect of the case is the role of cigarette smoking.

In summary, the cause of the intracerebellar hemorrhage in this case is unexplained.

Some of the broader implications of this case have been outlined. The incidence of this condition can be approximated from the series reported by Sims et al.[2] They found prelabor intracranial hemorrhage and gliosis in about 6% of stillbirths. Stillbirth occurs in less than 1% of pregnancies, thus such a condition may occur in approximately 5 per 10,000 pregnancies. In contrast to this, legal suit is filed in such cases in close to 100% of cases, so it is critical that such cases be appropriately diagnosed, as was done in this case with fetal ultrasonography, to ensure than the health care providers are not inappropriately blamed for misdiagnosing intrapartum fetal asphyxia.

We do not always have the luxury of such data, but we do have the possibility of ruling out intrapartum asphyxia in almost all cases. Intrapartum asphyxia can be ruled out if (1) the umbilical arterial acid-base state and blood gases are normal, (2) the Apgar score is normal (above 7 at 5 minutes), (3) there is normal fetal heart rate variability within several minutes of delivery, and (4) seizures do not occur in the first day or two of life.

The authors ruled out intrapartum asphyxia with cord blood acid-base state studies.

2. Sims ME, Turkel SB, Halterman G, Paul RH. Brain injury and intrauterine death. AM J OBSTET GYNECOL 1985; 151:721-3.

DR. PETER WATSON, Portland, Oregon. I concur with Dr. Parer's remarks about the importance of obtaining cord blood gas levels whenever there is an abnormal fetal heart rate tracing and the possibility of an abnormal outcome. Obtaining cord blood gas levels helps much more than it hinders us in those medicolegal circumstances when it is very difficult to determine cause and effect.

I would like to suggest maternal cocaine abuse as a possible cause for the neonatal outcome in this case. The incidence of maternal cocaine abuse is rising and its association with intracerebral bleeding is well documented.[1] I wonder if a drug screen was obtained in this case. A drug screen is obtained in our institution in the event of any unexplained fetal or neonatal bleeding. A maternal urine sample positive for cocaine in this particular situation would not only explain the circumstances but would also do much to avoid litigation.

REFERENCE

1. Mercado A, Johnson G Jr, Calver D, Sokol RJ. Cocaine, pregnancy, and postpartum intracerebral hemorrhage. Obstet Gynecol 1989;73:467-8.

DR. RUSSELL LAROS, San Francisco, California. Along the same line, Dr. Jennett, I assume laboratory studies were done on the infant to study the whole variety of coagulation abnormalities that could explain the bleeding. You did not mention platelet count, congenital hypofibrinogenemia, or congenital hypoprothrombinemia. Were all clotting factors evaluated and

was the mother questioned about the use of antiplatelet agents, such as aspirin or diuretics?

Dr. Jennett (Closing). We have agonized over this case and greatly appreciate the suggestions that have been made concerning possible causes. Dr. Parer, I can measure the interval with a calipers and say that there is no question that these are late decelerations. They do not fit any other category. There was not a great length of time between discontinuation of oxytocin, reduction of contractions, and the cesarean section. I keep trying to think of an imaginative explanation that would prove the experts wrong and demonstrate late decelerations caused by head compression. This woman smoked heavily and her cigarette smoking was a source of a great deal of concern to us. Unfortunately, I cannot quote statistics on the incidence of intracerebellar hemorrhage.

Dr. Watson asked about blood gas levels. I suppose with our worry and consternation, the blood gas laboratory ran only the cord pHs. However, the umbilical cord was immediately catheterized and the blood samples obtained showed no deviation from accepted levels of carbon dioxide and oxygen. The infant was definitely not metabolically acidotic. Your question of maternal drug use, especially of cocaine, is certainly an intriguing and pertinent one. In this case, no drug screen was obtained. Our hospital has wrestled with the question of performing drug screenings without permission and it has unfortunately decided that such screenings will not be allowed. We have good reason to believe that in our affluent area, cocaine usage is greater than in many areas, such as Los Angeles, that get a "bad press."

Dr. Laros, no history of the use of antiplatelet medications was sought and no coagulation studies were done.

Myomectomy as a reproductive procedure

Donald C. Smith, MD, and Jane K. Uhlir, MD
Seattle, Washington

This series of 64 myomectomies describes the indications, technique, and efficacy of the procedure; the majority of operations were performed on large multinodular uteri. Indications included enlarging pelvic mass, menorrhagia, anemia, and pregnancy wastage in women who wished to preserve reproductive capability. Although infertility was not the primary indication in any case, 32 patients were nulligravid. Only 10 patients were parous and 14 had a history of spontaneous abortion or pregnancy wastage. The average age of the patients was 35.8 years (range, 27 to 47 years). There were no major complications and no patients received blood transfusions. Follow-up revealed three patients with recurrent tumors necessitating repeat procedures. Successful pregnancies have occurred in 40% of those attempting pregnancy. It is concluded that successful myomectomy can be performed in most patients regardless of uterine size, thereby preserving reproductive potential. (Am J Obstet Gynecol 1990;162:1476-82.)

Key words: Myomectomy, fertility, fibroids

Although myomectomy was introduced to gynecologic surgery nearly 150 years ago, it has been during recent years that it has become an increasingly important procedure performed with greater frequency. This increased use of myomectomy rather than hysterectomy results from the desire and necessity of patients to retain or improve reproductive potential. There are several reasons for this, the most important of which follow. Today there are generally fewer adoptive infants available to the infertile couple or patient after hysterectomy than in the past. Delaying attempts at pregnancy until a later maternal age has exposed many women to the increased prevalence of uterine myomas before conception. Finally, there is no current medical treatment to accomplish the permanent removal or resolution of uterine leiomyomas. In addition to these reasons, many women (whether they plan to attempt pregnancy or not), for various psychologic, emotional, or cultural reasons, are reluctant to proceed with hysterectomy and wish to preserve the uterus.

Despite the reason, and limiting discussion primarily to the groups wishing to attempt subsequent pregnancy, the role of myomectomy as a reproductive-enhancing or -preserving procedure is clearly established.

Material and techniques

This article reports the experience of 64 myomectomies performed in 63 patients by the authors between Jan. 1, 1981, and Nov. 30, 1988 (Table I). The age range for the group was between 27 and 47 years, (average age, 35.8 years). Table II shows the number of procedures performed in 5-year age groupings.

Indications for myomectomy are shown in Table III. All patients were first seen with a pelvic mass, and the size of the uterus or a recent enlargement was the primary indication for surgery in 58 cases (uterine size, 12 weeks' gestational size or larger). In 37 patients, uterine size or recent continued growth was the only indication. These were instances in which the uterine size was usually significantly larger than 12 weeks' gestational size, and delay of myomectomy would result in a more difficult procedure, or in which the clinical setting suggested that subsequent attempts at achieving a successful pregnancy outcome would be jeopardized (e.g., cavity distortion, advanced maternal age, rapid growth of myomas). Ten patients had experienced 14 spontaneous abortions but only in four patients were the fibroid tumors thought to be directly related to the early pregnancy loss.

Infertility was not the primary indication in any patient, although 35 patients were nulligravid. The remaining 28 patients had been pregnant a total of 46 times, and 11 patients had been delivered 15 infants. There was a total of 15 spontaneous abortions; 11 occurred in 10 nulliparous women.

Table IV shows the comparative previous reproductive histories between those patients who attempted pregnancy after operation and those who did not. The

only significant difference was that there were more patients with accompanying pelvic inflammatory disease or endometriosis in the group attempting pregnancy.

Operative techniques

Although myomectomy is a procedure that has been performed by gynecologic surgeons for many years, a few comments on preoperative preparation and operative techniques are appropriate. Because most of the operations in this series were performed before gonadotropin-releasing hormone agonists were readily available to most clinicians, they were not used preoperatively in any case to induce shrinkage of tumors before operation as has been suggested.[1]

Preoperative hysterosalpingography is desirable in nearly all cases. This allows definition of cavitary involvement and identification of interstitial obstruction of the fallopian tubes or associated distal tubal disease if it is present. If intracavitary fibroid tumors are present, or if it is likely that the uterine cavity will be entered, a dark solution of indigo carmine or methylene blue should be instilled into the uterine cavity before incision. This is most easily accomplished by a transcervical cannula or catheter. This greatly aids in determining when the cavity has been entered and assists in avoiding undue damage to the endometrial surfaces.

It has been our belief that vigorous attention must be paid to hemostasis to allow the surgeon to carefully and accurately remove all tumors, reconstruct the myometrial defects, and obtain meticulous closure of the uterine incisions. Therefore whenever possible we place a circumferential lower uterine segment tourniquet consisting of a size 12-Fr red rubber catheter cinched tight with hemostats. This is not released until the uterine incisions are being closed or are closed. There have been no cases of postoperative shock as a result of accumulation of a histamine-like substance as suggested by Rubin[2] and Ranney and Frederick,[3] and we do not think that it is a potential cause of ischemic damage, as mentioned by Buttram and Reiter.[4] We also employ the liberal use of a vasoconstrictive agent (vasopressin, 20 units in 200 ml of sterile saline solution), injected into the myometrium surrounding the fibroid tumors. Use of thes ancillary procedures allows the surgeon to work in a nearly bloodless field.

Careful thoughts should be given to the placement of the uterine incisions. Midline uterine incisions are generally less vascular, but incision placement should be made so that as many tumors as possible can be removed through a single incision while avoiding the uterotubal junction. The greater concern of posterior uterine incisions, which may cause complicating adhesions more frequently, is not as important with the ac-

complishment of meticulous closure of the serosal incision.

Our choice of suture material for the myometrial reconstruction is 2-0 or 4-0 Vicryl (Ethicon, Inc., Somerville, N.J.) for the deeper layers and 4-0 or occasional 6-0 Vicryl for the uterine serosa. In general, as small a suture as possible is used, but the suture should be large enough to avoid breaking or cutting through the tissue if placed under significant tension.

Procedures for actual removal of the myomas use familiar techniques of blunt and sharp dissection with conventional instruments. We use loupe lens magnification in many instances, because it emphasizes careful dissection. Vigorous traction on the tumors should be avoided, particularly when they are located close to the endometrial cavity or interstitial tube.

During the course of the procedure the pelvis is irrigated with Ringer's lactated heparin solution, and before closure of the peritoneum, 100 ml of dextran 70 (Hyskon, Pharmacia Laboratories, Piscataway, N.J.) is instilled in the cul-de-sac. Routine antibiotics or corticosteroids or other agents to prevent adhesions were not used.

Results

During the interval of the study, myomectomy was successfully performed in all patients for whom it was scheduled. Hysterectomy, hypogastric artery ligation, or other procedures to control bleeding was not necessary in any case. The average length of hospital stay was 4 days (range, 2 to 7 days); this is consistent with most laparotomies. There were no major complications, such as pelvic abscesses or bowel obstructions, that necessitated additional lengths of stay. Only three of the 64 procedures necessitated a hospital stay of over 5 days. The range of operating time of 55 minutes to 3 hours 50 minutes (average, 2 hours) generally correlated with the number of tumors removed or with ancillary procedures performed.

Because of strict attention to hemostasis, no patient required blood transfusion. Estimated blood loss ranged between 200 and 400 ml, and the average drop in hematocrit 24-hours after operation was six points.

There was a wide range in the total number and total weight of myomas removed (Table V). Larger tumors were removed from the group of patients in whom uterine size was the sole preoperative indication.

Thirty-two of the patients have attempted to become pregnant after operation. For a variety of reasons, 27 of the women have elected not to attempt pregnancy at this time; the most common reason is that they were unmarried. Two patients have had subsequent hysterectomies, and current information is not available for two patients.

Of the 32 patients who attempted pregnancy, sixteen have achieved a single pregnancy. Twelve of these have resulted in term viable infants (40%). There have been two ectopic pregnancies (both in patients with associated pelvic inflammatory disease), and two pregnancies that ended in spontaneous abortions. The sixteen pregnancies that occurred are shown related to maternal age at time of delivery in Table VI. Half the patients who were delivered were age 35 years of age or older and five were age 40 or older. Two patients became pregnant by gamete intrafallopian transfer.

There was no correlation between the total weight of fibroid tumors removed and the likelihood of becoming pregnant. The average fibroid tumor weight of those who subsequently conceived was 224 gm, and in those who did not conceive average tumor weight was 190 gm.

Of the 62 patients for whom follow-up data are available, recurrent myomas have been detected in four (6.4%). The reappearance of tumors occurred after 5 years in three patients and after 4 years in one patient. These have resulted in hysterectomies in two cases and repeat myomectomy in one patient. The remaining case is currently being followed up.

Comment

This series of myomectomies was collected and presented to illustrate several points. Sixty-one of the 63 patients in the study were either attempting pregnancy or wished to preserve childbearing potential for the future. Within this group, we estimate that 20% to 25% of the cases were either referred or sought second opinions because other physicians recommended hysterectomy as a first choice or told them that there was no alternative. To the contrary, if subsequent pregnancy

is even a consideration, hysterectomy is not an alternative. Even with the advanced degree of sophistication of assisted reproductive technologies allowing pregnancies to occur without fallopian tubes or even ovaries, a successful pregnancy is not possible without a uterus.

In view of this, myomectomy must be offered to this large segment of patients, and should be performed with the same principles of atraumatic technique used in other fertility operations. This implies careful hemostasis, accurate closure and reapproximation of uterine incisions, and magnification when necessary to avoid damage to delicate uterotubal structures and to minimize postoperative adhesion formation. This point cannot be overemphasized; Berkely et al.[5] concluded that myomectomy itself may decrease fertility, probably as a result of adhesion formation.

The question of whether fibroid tumors cause infertility was not addressed directly in this series, although subsequent reproductive function is of primary interest. After operation 50% of the patients who attempted pregnancy have succeeded (16 of 32). This figure may be somewhat decreased by the fact that six of the 16 patients who did not become pregnant in this group had either chronic pelvic inflammatory disease or endometriosis in addition to leiomyomas.

Infertility alone was not the primary indication for operation in any case, but it is likely that some of the patients were indeed infertile. Although disagreement exists regarding the extent of the relationship between fibroid tumors and infertility, several recent studies[5-8] have reported on myomectomy as treatment for infertility, with pregnancy rates ranging between 50% and 65.2%, similar to those reported here.

Berkely et al.[5] reported only seven of 21 patients over the age of 30 who achieved pregnancy after myomectomy, whereas 18 of 29 patients under age 30 conceived; Babaknia et al.[6] reported that they had no pregnancy successes in women over the age of 35. However, in our half of the patients who became pregnant were 35 years of age or older, and 32% (5 of 16) were 40 years of age or older. These findings are similar to those of Rosenfeld[8] who reported that five of eight patients over age 35 and two of four patients over age 40 became pregnant. We found no significant difference in the total weight of fibroid tumors removed and achievement in pregnancy, which differs from the findings of Berkely et al.,[5] who found average total weight of fibroid tumors in those who ultimately conceived to be 194 gm compared with 384 gm in those who did not.

The possibility of recurrence of leiomyomas is a clinical consideration, especially when myomectomies are performed in younger women. In an extensive review by Buttram and Reiter,[4] 493 (15%) of 2554 patients had recurrent myomas, with 330 (10%) requiring subsequent treatment. In 62 patients for whom we have accurate follow-up data, four patients (6.4%) have had recurrent tumors and operation was required in three (4.8%). A rather short length of follow-up may account for these lower rates, but we attempt to remove all tumors encountered regardless of size.

In summary, the importance of the role of myomectomy in preserving reproductive capacity is emphasized. This implies that the procedure be available to every patient desiring it, and that it be performed in a manner that minimizes postoperative complications that could decrease desired results. Sixteen of 32 patients who attempted pregnancy succeeded, and half were aged 35 or older. The total weight of tumors removed did not correlate with pregnancy success. It is our conclusion that virtually any patient in the reproductive age range, regardless of uterine size, is an appropriate candidate for consideration for myomectomy.

Discussion

Dr. Howard A. Blanchette, Berkeley, California. Drs. Smith and Uhlir addressed a clinical problem that we as gynecologists confront daily in our practices. The challenge to preserve reproductive potential of women in the childbearing age group who are afflicted with leiomyomas necessitates myomectomy in any woman desirous of retaining her childbearing potential, or wishing to preserve her uterus for personal or cultural reasons.

The authors have emphasized the necessity to use the principles of infertility microsurgery in performance of myomectomy. They include preoperative evaluation with a hysterosalpingogram to allow definition of cavitary involvement and identification of interstitial obstruction of the fallopian tubves, or associ-

ated distal tubal disease. They also recommend instillation of indigo carmine or methylene blue into the uterine cavity before incision, to help in determining when the cavity has been entered. Intraoperatively a tourniquet is used circumferentially around the lower uterine segment and vasopressin, 20 units in 200 ml of sterile saline solution, is used liberally. Loupe lens magnification is also used. Fine suture material, ranging from 2-0 to 6-0 Vicryl, and meticulous attention to hemostasis is emphasized. Incisions are made in such a manner as to remove as many tumors as possible through a single incision, and serosal incisions are neatly closed. Intraoperatively the pelvis is irrigated with Ringer's lactated heparin solution; 100 ml of Hyskon is instilled in the cul-de-sac before closure of the peritoneum. Drs. Smith and Uhlir do not use routine antibiotics, corticosteroids, or other agents to prevent adhesions, nor do they use gonadotropin-releasing hormone agonist preoperatively to decrease vascularity and size of the uterus.

The results are impressive: 64 myomectomies over a time span of 7 years with no major complications, no blood transfusions, no intraoperative hysterectomies, average length of hospitalization of 4 days, 6.4% incidence of recurrent tumors, and, in those patients who attempt pregnancy, a 50% pregnancy rate with a 40% live-birth rate. Half of the pregnancies were in women over the age of 35.

Comparative results from my three-person private practice in obstetrics and gynecology in Berkeley substantiate these findings. Sixty-nine myomectomies were performed in a 10-year period from 1979 through 1989. There was little difference between the authors' patients and our patients with regard to previous reproductive performance, average age, indications for surgery, length of hospitalization, preoperative and postoperative hematocrit levels, numbers of tumors removed, and the weight of tumors removed.

However, differences were evident between the two groups in the use of hemostatic adjuncts. The authors routinely used a tourniquet and vasopressin, whereas in my group over a third did not have any hemostatic adjunct. This may have explained why three of our patients required intraoperative transfusion. Fourteen of our patients, contrasted with three of the authors' patients, had a length of stay greater than 5 days. The authors had no major complications, and we had two. One patient had postoperative endometritis that necessitated use of parenteral antibiotics, and another patient required intraoperative hysterectomy, not because of bleeding, but because the myomatous process was so extensive that meticulous excision would not preserve her childbearing potential. Four of our patients had excision of tumors that weighed more than 765 gm, which was the authors' upper limit; of interest is the one patient who had a 30-week size uterus, nine fibroids, with accumulative weight of 2640 gm. Sixteen percent of our patients had recurrent tumors, contrasted with 6.4% of the authors' cases.

The postmyomectomy reproductive performance in those patients who attempted pregnancy was similar in both groups; their group achieved a 50% pregnancy rate, and a 40% live birth rate, and our group achieved a 52% pregnancy rate with the same live birth rate. Half of their patients and one third of our patients who achieved pregnancy were over the age of 35.

The authors have stated emphatically that if a subsequent pregnancy is even a consideration in any woman with uterine leiomyomas, hysterectomy is not an alternative. They concluded that virtually any patient in the reproductive age range, regardless of uterine size, is an appropriate candidate for consideration for myomectomy. Recent studies in the literature addressing the enhancement of preoperative assessment and intraoperative management to improve the reproductive outcome of myomectomy include: (1) the preoperative use of magnetic resonance imaging to assess size and location of the fibroids, (2) the use of a gonadotropin-releasing hormone agonist preoperatively to reduce vascularity and size of the leiomyomas, (3) the use of the laser intraoperatively to improve hemostasis, reduce postoperative adhesion formation, remove myomas from previously inaccessible areas, and effect direct vaporization of smaller myomas, and (4) the judicious use of prophylactic antibiotics in instances when it is anticipated that the uterine cavity may be entered during the performance of myomectomy.

Controversy does abound in the literature regarding leiomyomas, infertility, and the role of myomectomy. I will outline the controversy by asking Dr. Smith the three following questions. (1) Should myomectomy precede attempts at conception if a documented submucous fibroid tumor is present? (2) At what uterine size should myomectomy precede attempts at conception? (3) In instances when a leiomyoma is the only finding in a couple's infertility evaluation, should myomectomy be performed?

Dr. Robert Israel, Los Angeles, California. In May 1935, Victor Bonney, consulting gynecologic and obstetric surgeon to the Middlesex Hospital, London, England, was the invited guest at the American Gynecological Society's annual meeting in Hot Springs, Virginia. In 1946 he thanked the fellows of that Society by dedicating to them his new book, *The Technical Minutiae of Extended Myomectomy and Ovarian Cystectomy.*[1] On the basis of his experience with over 800 myomectomies, the focus of the book is directed toward the various operative approaches that can be used depending on the location and size of the myomas encountered. If Victor Bonney were alive today, he would be delighted with this paper that not only espouses myomectomy, but clearly demonstrates that this operation can be performed with precision and attention to detail that will yield very low complication and recurrence rates.

Recent years have seen a great improvement but radical operations on the womb are still being carried out where conservatism would be equally feasible and safe; the surgeons who perform them being either timid of new ways or too confirmed

in the old, to change. I have no message for the suture-bound, nor for those whose capacity is already stretched to its utmost, but to those others I would say that surgery thus shorn of what should be its chief adornment, mercy, is a mean goal to aim at.[1]

Having praised the authors' study for its vision and excellent results, I would like to raise some questions and review some concepts that, hopefully, will make this an even stronger paper. As noted by the authors, all 64 patients who had myomectomies presented with a pelvic mass, and in 58 uterine size or a recent enlargement were the primary indications for operation. How many of the 58 cases were in each of these categories? Additionally, when does size become an indication? Although the authors discuss tumor weight, they did not mention what is clinically important preoperatively: uterine size. What was the breakdown of these cases by uterine size and how was "recent enlargement" evaluated? This information would seem to be relevant since none of the patients apparently presented with clinically important pain, pressure symptoms, or excessive bleeding.

Because combined surgical procedures often yield poorer results, one wonders whether the patient who underwent myomectomy with reversal of tubal sterilization maintained tubal patency and conceived? In the patient who underwent transabdominal myomectomy and metroplasty, where was the myoma(s) located, and, if it did not involve the uterine cavity, was consideration given to a hysteroscopic metroplasty to prevent the future need for cesarean section?

With no major complications, no blood transfusions, and the normal postoperative length of stay, it is obvious that we cannot quarrel with the authors' meticulously thorough operative technique. Bonney would be proud.

I have often thought how wonderfully perfect the surgery of the abdominal cavity would become, if we could send a team of trained Lilliputians down a ladder through the abdominal wound with instructions to get on with the job. What gentleness! What absolute hemostasis! What meticulous neatness of adjustment and suture! How little after-pain; not worse than a mild toothache. What safety! Gentleness is of great importance in myomectomy, for the hurried wrenching out of deeply-imbedded tumours shocks the patient and mauls the tissues.[1]

Drs. Smith and Uhlir for Lilliputians-of-the-Year!

The average drop in the postoperative hematocrit was 6 points. With the hemodilution usually observed after operation when 100 ml of dextran 70 are left in the pelvis, this hematocrit fall is not unusual. When was the postoperative hematocrit sample drawn?

Were the 12 infants who were born after myomectomy delivered vaginally or by cesarean section? If there were any cesarean sections, were they performed because the uterine cavity had been entered, or a significant portion of the myometrium violated, at the time of myomectomy? All the myomectomies were performed between 1981 and 1988. With the low rate of myoma recurrence, how many patients were followed up for how long (i.e., how many have been followed up 8 years, how many 7 years, etc?).

Although all of the authors' cases involved uterine myomata, they were fortunate that on occasion they did not encounter an enlarged adenomyomatous uterus rather than an enlarged myomatous uterus. If the planned operation is a hysterectomy, differentiating between the two is unimportant. However, if the planned operation is a myomectomy, finding adenomyosis when the uterine wall is incised leaves only one conservative alternative: Back out, closing the abdominal incision as you go. Fortunately, today we have magnetic resonance imaging that can differentiate between adenomyosis and myomas *before* operation. With use of a high index of suspicion, especially with a globularly enlarged uterus, preoperative magnetic resonance imaging, with even just a few sagittal views, will prevent you from starting a "myomectomy" on an adenomyomatous uterus. Could the authors explain their non–magnetic resonance imaging "skills" and could they also give their opinion on magnetic resonance imaging use?

Given the lack of any significant cases of menorrhagia, one wonders whether the Seattle weather does not permit the development of submucous myomas or, in actuality, there were no submucous lesions? The difficult myoma cases involve a combination of submucous myoma(s), menorrhagia, and anemia. With the clinical availability of at least one gonadotropin-releasing hormone agonist, the bleeding can be stopped, thus allowing the anemia to be corrected with iron therapy, and the myoma(s) can be reduced to a size that can be handled hysteroscopically or through a Pfannenstiel skin incision, in contrast to the authors' midline vertical approach. Although no blood transfusions were necessary in this study, they are potentially necessary in all myomectomies. Autologous blood use is the preferred method of intraoperative and postoperative blood replacement. Even in the patient with menorrhagia, the use of a gonadotropin-releasing hormone agonist can create an amenorrheic state and allow restoration of a normal hemoglobin level and the ability to self-donate blood.

In 1946, Victor Bonney[1] wrote: "Very few cases of fibroids are now beyond the technical range of myomectomy. There is a pleasure, a pride, and a satisfaction in these conservative operations which cannot be appreciated save by those who have performed them, and I want to see them in the repertory of every surgeon called upon to operate on the womb."[1]

Forty-three years later, Bonney would revel in Smith and Uhlir's last sentence: "It is our conclusion that virtually any patient in the reproductive age range, regardless of uterine size, is an appropriate candidate for consideration for myomectomy."

Dr. Smith (Closing). All questions posed by Drs. Israel and Blanchette are important and appropriate; however, time constraints preclude addressing most of them. I will comment briefly on a few of their questions.

To clarify Dr. Israel's comments, we do not use vertical abdominal incisions. The incisions I alluded to are vertical uterine incisions. In regard to the use of magnetic resonance imaging for the definition of myoma as opposed to adenomyosis, I believe that use of ultrasonography and pelvic examination, together with presenting complaints, is sufficient to differentiate between the two disease entities and is more economical. In our series we have encountered adenofibromas but no frank cases of adenomyosis.

With regard to Dr. Blanchette's three questions, I have no definite answers to these clinical dilemmas. In a patient with a submucous myoma, unless it marked distorts the cavity, an attempt at pregnancy is probably justified before myomectomy. Although the age of the patient, size of the fibroid tumor, and the total clinical setting must be considered, I have seen patients with prominent lower-segment fibroids carry pregnancies to term.

At what uterine size do we choose to intervene? There is no definite answer. I believe that uterine sizes larger than 12 to 14 weeks' gestational size begin to be more technically difficult, and allowing the uterus to grow beyond this point may produce a more difficult procedure. I would perform a myomectomy at that time, even if the patient was going to defer pregnancy attempts to some later date.

The last question regards the infertile patient and fibroid tumors. If you think your evaluation is complete, no other cause has been uncovered, and more conservative therapeutic approaches have been unsuccessful, then, and only then, should myomectomy be considered.

Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting

Sheila J. DiMarzo, PhD, Janet Huang, MD, Joseph F. Kennedy, MD, Benito Villanueva, MD, Stephen A. Hebert, MD, and Philip E. Young, MD

San Diego, California

From late 1970 through December 1987, 580 women began 733 treatment programs (a total of 3405 insemination cycles) with fresh semen for artificial insemination by donor. The unadjusted pregnancy rate was 48.5% and the cumulative pregnancy rate after seven cycles by life-table analysis was 59.6% with a monthly fecundability of 11.9%. From 1988 to the present, 113 women have begun 115 treatment programs (a total of 371 insemination cycles) with cryopreserved semen for artificial insemination by donor. The unadjusted pregnancy rate to date is 18.3% and the cumulative pregnancy rate after seven cycles by life-table analysis is 48.6% with a monthly fecundability of 5.9%. This report shows that using cryopreserved semen for artificial insemination by donor will take somewhat longer to produce a pregnancy but the ultimate pregnancy rate will be similar to that with fresh semen for artificial insemination by donor. (AM J OBSTET GYNECOL 1990;162:1483-90.)

Key words: Artificial insemination by donor, fresh artificial insemination by donor, cryopreserved artificial insemination by donor, pregnancy rates

Artificial insemination by donor (AID) has been practiced at The Fertility Institute since late 1970. During most of this time fresh semen was used. This required the careful timing of donor and patient appointments, made weekend inseminations impractical, and often led to disappointment in patients when donors were unavailable for subsequent pregnancy attempts. In 1987 we began the use of a computerized staged-freezing technique for the purpose of semen cryopreservation. Our initial intention was to use cryopreserved semen as a "backup" to make AID more readily available and convenient for our patients and to provide an opportunity for a controlled comparison of the efficacy of fresh versus frozen semen. However, the American Fertility Society published recommendations in February of 1988 advising against the use of fresh semen for artificial insemination because of the increased risk of sexually transmitted diseases (particularly acquired immunodeficiency syndrome).[1] As of that date *only* cryopreserved, 6-month quarantined specimens have been used for AID in our program.

The resulting abrupt switch from using fresh semen to using cryopreserved semen did not allow us the opportunity to do a study controlling all variables and using the patient as her own control with alternating cycles of fresh or cryopreserved semen for insemination with the purpose of comparing the pregnancy rates achieved. Because of this, many factors do vary between the two populations studied. For example, when AID was begun in our practice in 1970, basal body temperature measurement was the standard means of ovulation detection with two inseminations per cycle recommended to cover the time of ovulation. As technology improved, luteinizing hormone measuring became more readily available to pinpoint ovulation more accurately and inseminations were often decreased to once per cycle. Consequently many AID cycles with fresh specimens had two inseminations to adjust for a less accurate predictor of ovulation time while cycles with cryopreserved specimens usually had one very carefully timed insemination. Although these methodologic changes over the years result in groups that are not strictly comparable, we felt that it was nevertheless useful to make retrospective comparisons between the pregnancy rate with fresh semen (inseminations done between 1970 and 1988) and that using cryopreserved semen (1988 to the present). This article makes that comparison and discusses possible reasons for the differences that exist.

Material and methods

A treatment program is defined as a series of one or more essentially sequential monthly cycles of insemi-

G ≥ 1, P0	26.9	26.1
G ≥ 1, P ≥ 1	26.7	30.4

nation in one patient for the purpose of achieving a pregnancy. From late 1970 through December 1987, 580 women began 733 treatment programs of artificial insemination with fresh donor semen (consisting of from one to more than 20 cycles) at The Fertility Institute (Infertility, Gynecology and Obstetrics Medical Group of San Diego) for the purpose of achieving a pregnancy. From January 1988 to the present, 113 women have begun 115 treatment programs of artificial insemination with cryopreserved semen (consisting of from one to ten cycles) for the purpose of achieving a pregnancy. The patients in both groups ranged in age from 20 to >40 years old. Some had never been pregnant while others had achieved previous pregnancies (Table I). The two groups of women were not different in terms of their reproductive history ($p > 0.20$ by χ^2 analysis), but the treatment group that received cryopreserved semen for AID was significantly older ($p < 0.001$ by χ^2 analysis) than the group that received fresh semen for insemination. Infertility workups were generally begun only after 6 months of failed AID but ovulation was always documented in insemination cycles. Some patients were in the midst of their treatment programs when the switch was made from fresh to cryopreserved semen. These patients were included in the fresh AID study group for all cycles in which fresh AID was done. They were not, however, included in the cryopreserved AID study group since they could not be regarded as new patients beginning a treatment program. There have been several pregnancies from cryopreserved AID in this group of patients who had previous cycles of fresh AID. These pregnancies are not included in any of the statistics in this report.

Donors were recruited from the local medical and graduate school programs, and these donors were required to meet all of the standards recommended by the American Fertility Society in the policy statement entitled Minimal Genetic Screen for Gamete Donors.[2] Donors were always initially and periodically tested for sexually transmitted diseases and, subsequent to the publication of the New Guidelines for the Use of Semen for Donor Insemination (American Fertility Society[3]), all testing recommended therein was performed. This included the quarantining of all frozen semen for 6 months, after which time the donor was retested for sexually transmitted diseases (especially human immunodeficiency virus) before the specimens were released for use.

Cryopreservation of semen was performed by adding to the liquified semen either 10% glycerol (Sigma Chemical Co., St. Louis) or an equal volume of Test-Yolk buffer solution (Irvine Scientific, Irvine, Calif.). Aliquots of the semen mixture were put into plastic Nunc vials and cryopreserved in a controlled temperature freezing chamber (model 1010 controller and model 990C freezing chamber; CryoMed, Mt. Clemens, Mich.). The temperature was lowered at 1° C/min to −4° C sample temperature (ramp 1), 25° C/min to −40° C chamber temperature, and then 15° C/min to −12° C chamber temperature (ramps 2 and 3, to allow for sample latent release of heat), 1° C/min to −40° C chamber temperature (ramp 4), and finally 10° C/min to −90° C (ramp 5). At the end of the freezing cycle the vials were plunged into liquid nitrogen where they remained until use.

Either one or two inseminations were performed in the periovulatory period as timed by basal body temperature measurements or luteinizing hormone testing. Inseminations with cryopreserved specimens were always timed by luteinizing hormone testing to define more precisely the time of ovulation since there is some concern that frozen-thawed sperm may have a shorter time of viability. Insemination occurred approximately 24 hours after the detection of a luteinizing hormone surge. Each intracervical insemination consisted of either an entire fresh specimen or a cryopreserved specimen containing a minimum number of motile sperm. Although each fresh specimen did not have a sperm count, specimens were periodically checked to ensure a sperm count of at least 30 million per milliliter with 50% motility. However, vagaries of fresh semen usage are such that it is unlikely that every specimen used for every patient met these criteria. Until February 1989 each cryopreserved specimen was required to have at least 12.5 million motile sperm after thawing. If a specimen did not meet this criterion, additional vials were thawed until the minimum was met. After February 1989 the minimum was increased to 20 million motile sperm after thawing. A few cycles consisted of intrauterine inseminations of washed sperm if indicated by the patient's diagnosis. With fresh semen the entire specimen was washed, while with cryopreserved semen the prewash motile sperm count was at least 20 million before February 1989 and 40 million after that date. This very small number of intrauterine insemination

patients was not separable from the "plain" AID specimens in our data collection method and they have been included in the statistics for their respective groups (fresh versus frozen).

Comparisons of the pregnancy rates for inseminations with fresh versus frozen semen were made by the statistical methods described in detail by Cramer et al.[4] Life tables (limited to the first 10 insemination cycles since data for AID with cryopreserved semen are not yet available beyond that point) were constructed and monthly fecundabilities were determined. The Z test was used to compare the monthly fecundabilities and χ^2 analysis was used for other comparisons.

Results

Table II gives the results of the two treatment programs listed by the number of insemination cycles completed by each patient. For the patient population receiving fresh semen for insemination, there were 356 pregnancies among 733 treatment programs started for an unadjusted pregnancy rate of 48.5%. These 733 treatment programs included a total of 3405 insemination cycles for an average monthly fecundability of 10.5%. For the patient population receiving cryopreserved semen, there were 21 pregnancies among 115 treatment programs started, for an unadjusted pregnancy rate of 18.3%. These 115 treatment programs included a total of 371 insemination cycles, for an average monthly fecundability of 5.7%.

The life-table analyses for the cumulative probability of pregnancy from AID with either fresh or cryopreserved semen are shown in Tables III and IV. In Table III the cumulative probability of pregnancy from AID with fresh semen reaches 59.6% at seven cycles and 67.9% at 10 insemination cycles. This life-table analysis estimates the monthly fecundability as 11.9% with a 95% confidence interval of 10.6% to 13.1%. In Table IV the cumulative probability of pregnancy from AID with cryopreserved semen reaches 48.6% at seven insemination cycles, and the number of patients undergoing more than seven cycles is so small that interpretation beyond that point is not statistically valid. The life-table analysis estimates the monthly fecundability as 5.9% with a 95% confidence interval of 3.4% to 8.4%. The difference in fecundability between AID with fresh semen versus AID with cryopreserved semen is significant by the Z test ($p < 0.001$).

Fig. 1 depicts the cumulative probability of pregnancy after AID with either fresh or frozen semen. For the patient population receiving fresh semen the probability of pregnancy is 16.2% after one insemination cycle and rises slowly to 59.6% after seven cycles. The probability of pregnancy for those patients inseminated with cryopreserved semen, which also rises slowly but

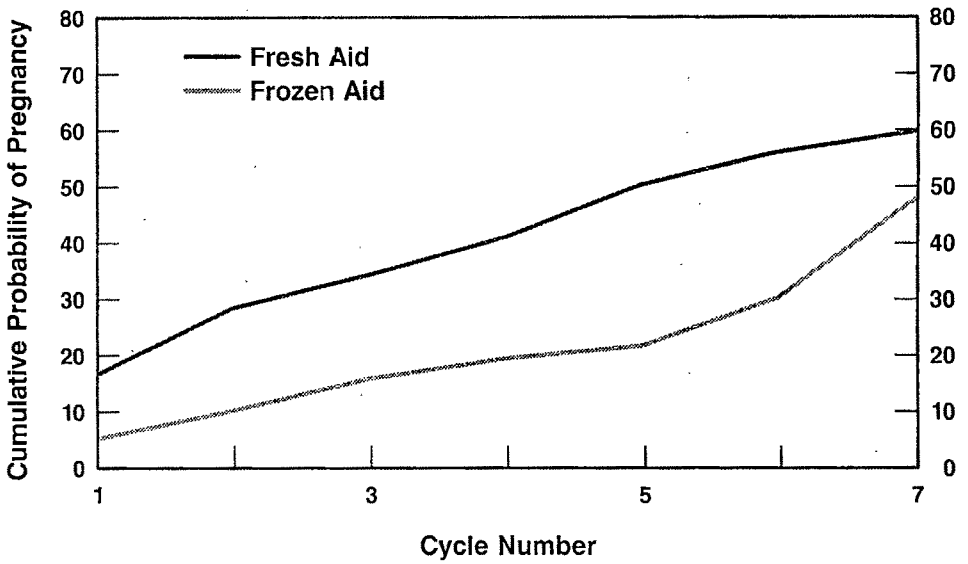

Fig. 1. Cumulative probability of pregnancy from AID with fresh or frozen semen: Life-table analysis.

is always less than that found after the same number of cycles using fresh semen, is 5.4% after one cycle and climbs to 48.6% after seven cycles. The difference between the cumulative probabilities of pregnancy with fresh or cryopreserved semen after seven insemination cycles (59.6% vs 48.6%) is of borderline significance ($0.02 < p < 0.05$ by χ^2 analysis).

Comment

When our program of semen cryopreservation began, we sought to optimize the cryopreservation techniques used. A computer-controlled staged freezing apparatus was used since it had been demonstrated that such a freezing protocol was superior to simple vapor freezing.[5] Glycerol was used as the cryoprotectant because of its demonstrated effectiveness, ease of availability, and small effect on the volume of the specimen.[5,6] After some experience with the 10% glycerol freezing protocol, we chose to switch to a commercially available cryoprotectant containing yolk buffer in the hope of improving the postthaw recovery of sperm motility.[7] Although this cryoprotectant does necessitate the 1:1 dilution of the semen specimen, we have found it to be superior to 10% glycerol since the recovery of motile sperm is greater. Initially we used a minimum acceptable number of motile sperm after thawing for an insemination of 12.5 million mainly because of the limited supply of quarantined specimens. As our inventory increased, this was raised to 20 million on the basis of indications that this might significantly increase the chances for achieving pregnancy.[8,9]

Monthly fecundability rates for inseminations with fresh semen reported in the literature range from slightly above 10% to >25% while the rates for inseminations with cryopreserved semen are somewhat lower, ranging from 5% to about 15%.[7,9,10-13] Our results are comparable to those in these reports.

In this study the overall unadjusted pregnancy rate for AID with cryopreserved semen is considerably lower than that for AID with fresh semen (18.3% vs 48.5%). This difference in the study is artificial and is explained by the fact that AID with cryopreserved semen is a fairly recently begun and ongoing study while the fresh AID study is complete. This is demonstrated by the fact that in the study of AID with cryopreserved semen 60% of the patient's treatment programs are still ongoing with fewer than six insemination cycles completed while at the termination of the study with fresh semen less than 5% of the treatment programs were still ongoing with fewer than six completed cycles. Thus 60% of the patients in the cryopreservation program have not yet had a "fair try" at AID and should therefore not be viewed as treatment failures. This information and that found from the life-table analyses lead us to believe that the overall pregnancy rates for AID with fresh versus cryopreserved semen will be comparable but that it will take more insemination cycles to achieve that overall pregnancy rate when cryopreserved semen is used. This conclusion is further supported by the fact that the treatment group that received cryopreserved semen is significantly older ($p > 0.001$) than the group that received fresh semen. Since the overall fertility rate decreases as a woman ages, it is likely that the difference in the cumulative pregnancy rates, independent of patient's age for fresh versus cryopreserved semen used for AID, is even smaller than our results suggest.

In the hope of further improving the pregnancy rate

per cycle when cryopreserved semen is used, we plan to further increase the number of motile sperm used per insemination since recent studies have shown increasing pregnancy rates as the motile sperm number is increased to ≥40 million.[7,9] It is important to realize that because of the increased specimen volume created by the cryoprotectant used for freezing and the resulting impracticality of performing an insemination with the entire number of sperm present in a single fresh ejaculate, by definition all frozen inseminations provide a lesser average number of motile sperm than do fresh specimens. It seems likely that the lower fecundability rate of frozen specimens per cycle is largely due to the fact that fewer total motile sperm are used per insemination rather than to any intrinsic deficiency introduced into the surviving sperm by the freezing process. This decreased total motile count per specimen is theoretically correctable by using only donors with unusually high initial counts and good thaw survival characteristics to increase the number of motile sperm per cryopreserved semen insemination. Unfortunately this approach is limited by the relative scarcity of such donors. Another possible approach, which has been used successfully elsewhere, would be to inseminate with a higher number of motile sperm and to concentrate the specimen by centrifugation before freezing if the volume is too great.[7] It must be kept in mind, however, that there is always a loss of sperm during a centrifugation step.

Because of the retrospective and purely clinical nature of this study, the population groups have not been controlled for variables such as patient age, potential causes of infertility, or gravidity and parity. Table I does examine the relative occurrence of some of these factors; however, as the patient group receiving cryopreserved semen completes the study, these variables will be examined in more detail.

In conclusion, artificial insemination with semen specimens cryopreserved with a computerized staged freezing technique, where the minimum postthaw total motile sperm count was 12.5 to 20 million, has been retrospectively compared to insemination with fresh semen specimens. The fecundicity rate per cycle is less for the frozen specimens (5.9% vs 11.9%, $p < 0.001$), but the difference in the cumulative probabilities of pregnancy after fresh or cryopreserved semen inseminations after seven cycles is of borderline significance (59.6% vs 48.6%, $0.02 < p < 0.05$). Since the group that received cryopreserved semen specimens is significantly older ($p < 0.001$), this difference is likely to be artifactual. Thus, with frozen specimens prepared in this manner, it will take somewhat longer to achieve a pregnancy but the ultimate pregnancy rate for the two populations should be the same. Careful preselection

of donors for semen cryopreservation to maximize the postthaw sperm counts so that the minimum number of motile sperm used per insemination will more closely approach the "normal" of fresh specimens may reduce or eliminate the apparent difference in the fecundicity rate per cycle between the two methods.

Discussion

Dr. Kenneth A. Burry, Portland, Oregon. This paper by Dr. Young and his colleagues is timely and important to those of us who treat infertile couples. Artificial insemination by donor is a well-accepted procedure to overcome infertility because of a severe male factor. The risk of transmitting AIDS warrants strict guidelines for the selection of donors and the preparation and use of semen.

Cryopreservation of semen is successful, allowing storage of semen for an indefinite period. Most centers quarantine semen for 6 months and release it for use if the donor remains seronegative for HIV. It is assumed that 6 months is an adequate time to follow up the donors.

The risk of using frozen semen is the possibility of not achieving pregnancy. Richter et al.[1] report lower fecundity rates with frozen semen than with fresh semen. Dr. Young's paper also reports a monthly fecundability of frozen semen to be one half that of fresh semen, 5.9% compared with 11.9%. The cumulative pregnancy rates were different after seven insemination cycles; however, the authors downplay this difference because of the age differences between the two groups of patients. The cumulative probability of pregnancy reported in this paper is 0.486 at 10 months for frozen semen and 0.515 at 5 months for fresh semen. Therefore with more cycles of insemination the pregnancy rates are similar, but it takes twice as much time.

The number of total motile sperm used for insemination is a critical factor. In this article Dr. Young reports on the use of 12.5 to 20 million motile sperm. Nielsen et al.[2] define 20 million motile sperm as the minimum number. These authors had no pregnancies when <12 million motile sperm were used. Comparing fresh with frozen semen, Bordson et al.[3] found no decrease in fecundability when using a total of 40 million, grade 3, motile sperm. Hammond et al.[4] used 60 million motile sperm with similar results; however, the fecundity was low in both groups of patients. Brown et al.[5] demonstrated a significant increase in fecundability with >100 million motile sperm compared with <100 million motile sperm.

The site of insemination may be another critical factor in fecundability rates. Similar fecundability rates occur with eight times fewer sperm with an intrauterine site of insemination. With fresh semen, Patton et al.[6] report a fecundability of 0.185 with an intracervical site and 151.2 ± 20.6 million motile sperm. In comparison, the fecundability of an intrauterine insemination was 0.148 with 18.3 ± 2.9 million motile sperm. It is important to know the number of total motile sperm before insemination, especially if a sperm wash-rinse was done. Intrauterine insemination with a minimum of 24 million motile sperm resulted in a monthly conception rate of 0.24. The conception rate was not further increased by doubling the sperm number.[7] At the Oregon Health Sciences University, a prospective study comparing intracervical insemination, intrauterine insemination, and intratubal insemination is being done. The site of insemination and the critical number of sperm required to achieve pregnancy within the shortest time are the questions to be answered.

I would like to ask Dr. Young the following questions:

1. How many women were inseminated with 12.5 million motile sperm and how many were inseminated with 20 million motile sperm? Were there enough women in each group to compare fecundability rates?
2. Similarly, how many women were in each of the

two intrauterine insemination groups, 20 versus 40 million? Was there a difference between these groups?
3. How many women received intrauterine insemination versus intracervical insemination, and was there a difference?
4. How many inseminations were done per cycle?
5. What were the mean ages per group? It appears that the age difference between the groups is significant; however, there is a 10-year range between 25 and 34 years. More important, what were the ages of the women who conceived? Were pregnancy rates compared between age groups?
6. Was there a difference in ovulation problems requiring ovulation induction between the groups?
7. When do you evaluate tubal and peritoneal factors by hysterosalpingography and laparoscopy? In view of the longer time required to achieve a pregnancy with frozen semen, should the evaluation of these women be different than when fresh semen is used?
8. Finally, will you comment on the total number of motile sperm and possibly the site of placement of sperm as important factors in achieving pregnancy?

DR. G. DAVID ADAMSON, Palo Alto, California. I have been performing donor insemination in my practice for 9 years. I used fresh sperm exclusively until February 1988 when the American Fertility Society revised its guidelines for donor insemination and recommended the use of frozen sperm. At that time, because of our concern over reduced fecundity with frozen sperm (to approximately 40% of that with fresh sperm in most studies in the literature), we decided to undertake a prospective randomized study comparing the pregnancy rates with fresh and frozen sperm. After approval by an investigational review board, we have conducted this study for the past year and a half. We screen donors for human immunodeficiency virus on a monthly basis with the polymerase chain reaction deoxyribonucleic acid gene amplification test, which costs about $200 per donor per month. We also screen for all sexually transmitted diseases every month. We feel that this provides a very safe situation for the patients. Data in the literature suggest the risk of human immunodeficiency virus infection is in the order of 1 in 500 million per insemination in this situation. So far our data show that fecundity is 19.6% per month with fresh sperm and 9.4% with frozen, a ratio of 48%.

The fecundity with frozen sperm being only half as high as that with fresh is a major issue. Most studies in the literature show that couples attempt donor insemination on average of only about four cycles. If you have to have eight cycles to get the same pregnancy rate with frozen sperm, many more couples will have discontinued treatment before being successful. The reduced fecundity also becomes an issue in patients who have reduced fecundity, for example, those with endometriosis, tubal disease, or older age. Dr. Young, have you any comments on the potential use of fresh sperm in these situations, especially in view of current diagnostic techniques for infectious diseases?

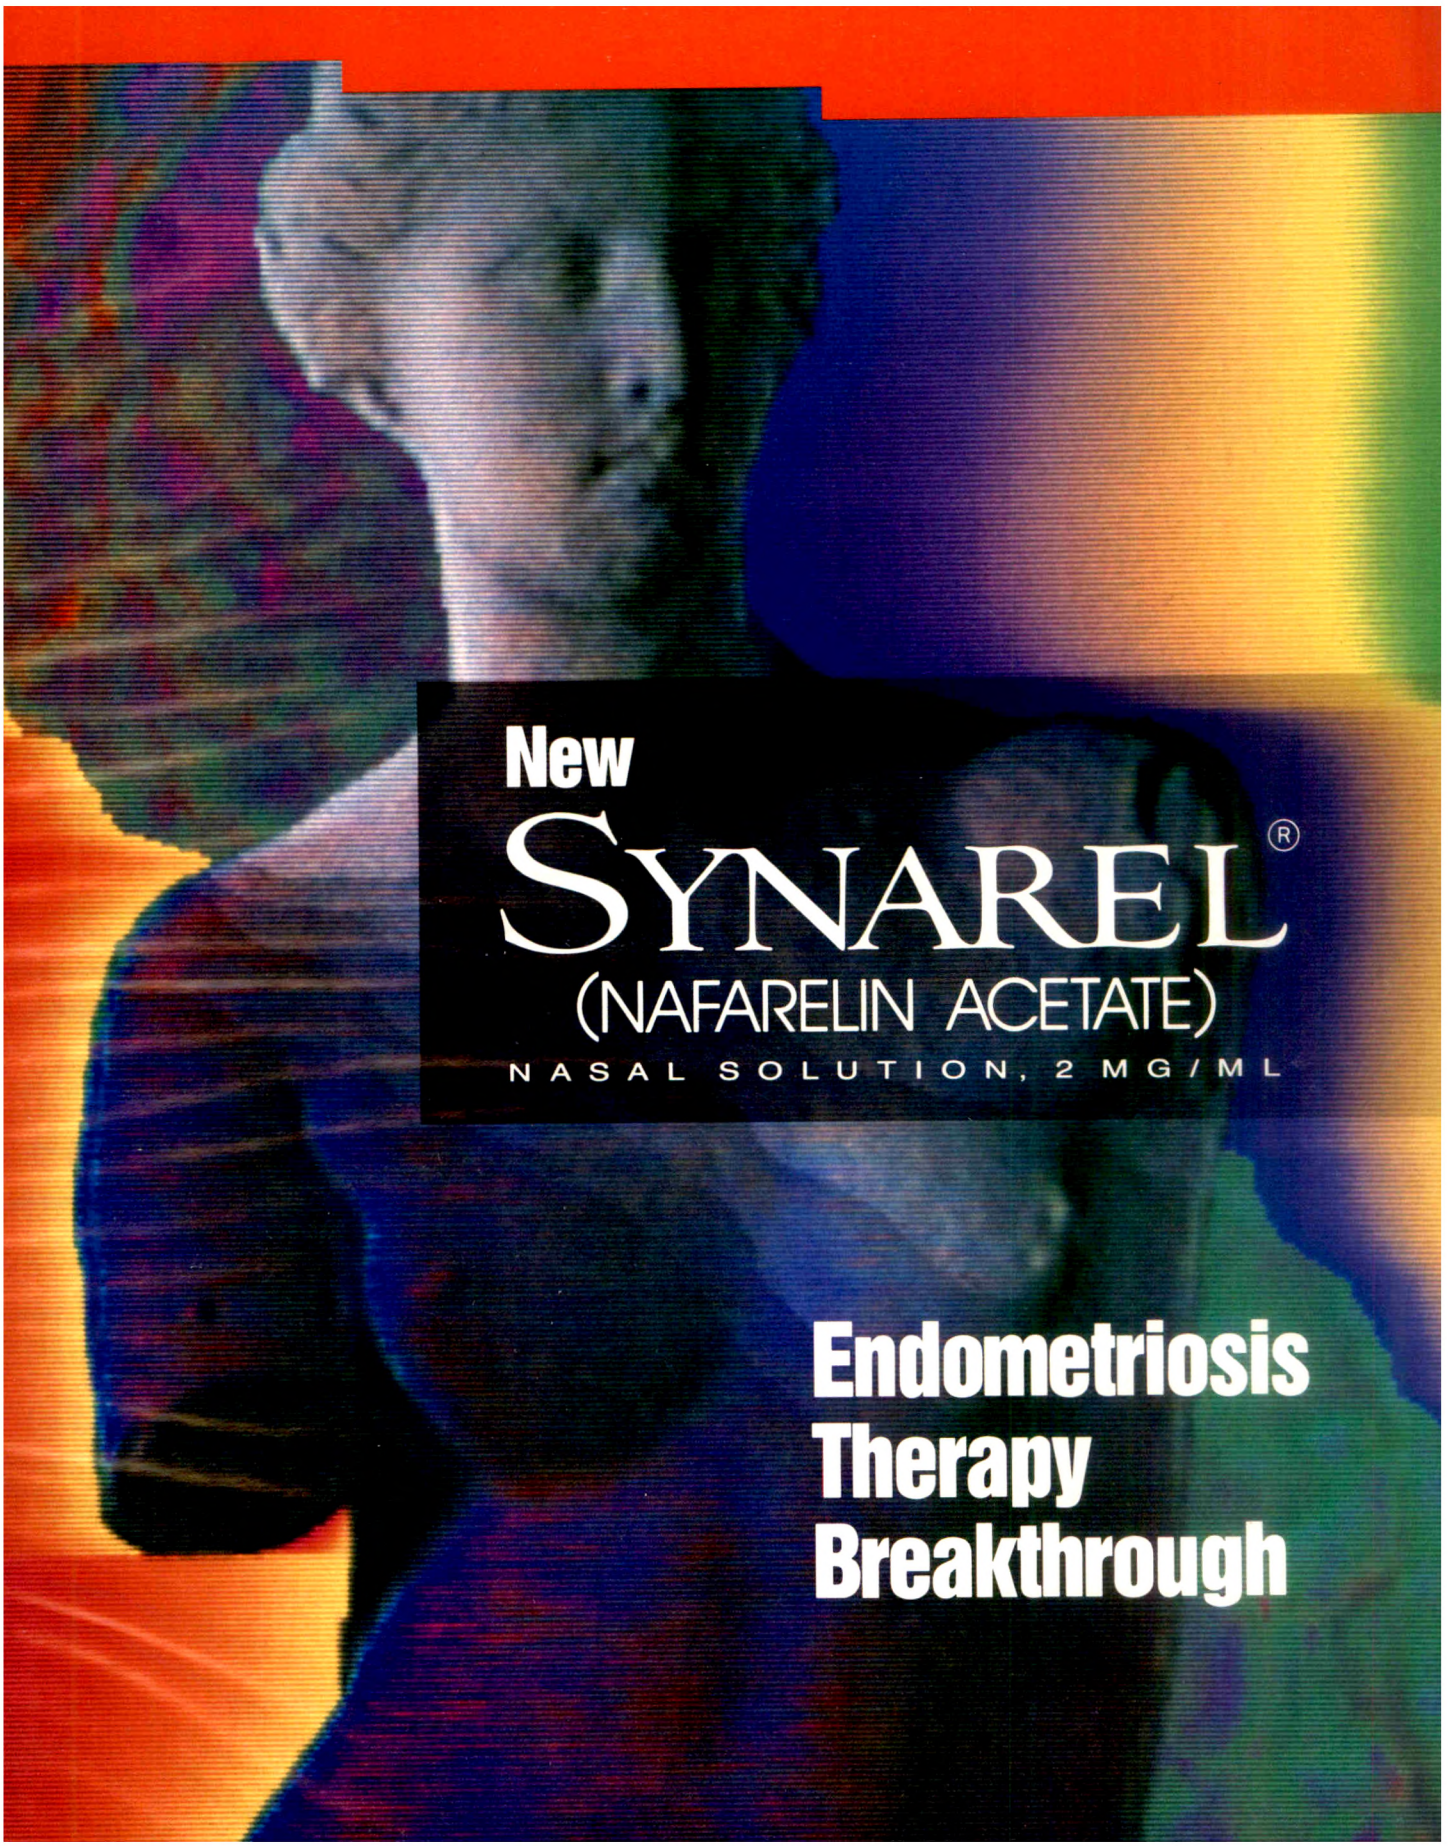
DR. FRED HANSON, Davis, California. Since 1974 we have had a large donor insemination program at the University of California, Davis. We also have had a fresh semen research protocol approved by our investigational review board, and our success rates are in line with those reported by Dr. Adamson.

Our group has been very concerned about differences in the span of time during which frozen and fresh sperm maintain the ability to fertilize an egg in vivo. This relates not only to the timing of insemination but also to the ability to withstand the laboratory preparation for intrauterine insemination. In our experience, some of our patients, who use the OvuQuick ovulation detection kit, already have ruptured follicles as determined by ultrasonography on the day of luteinizing hormone surge. When using frozen sperm, we are starting to switch to a policy of insemination both on the day of the color change and 24 hours later.

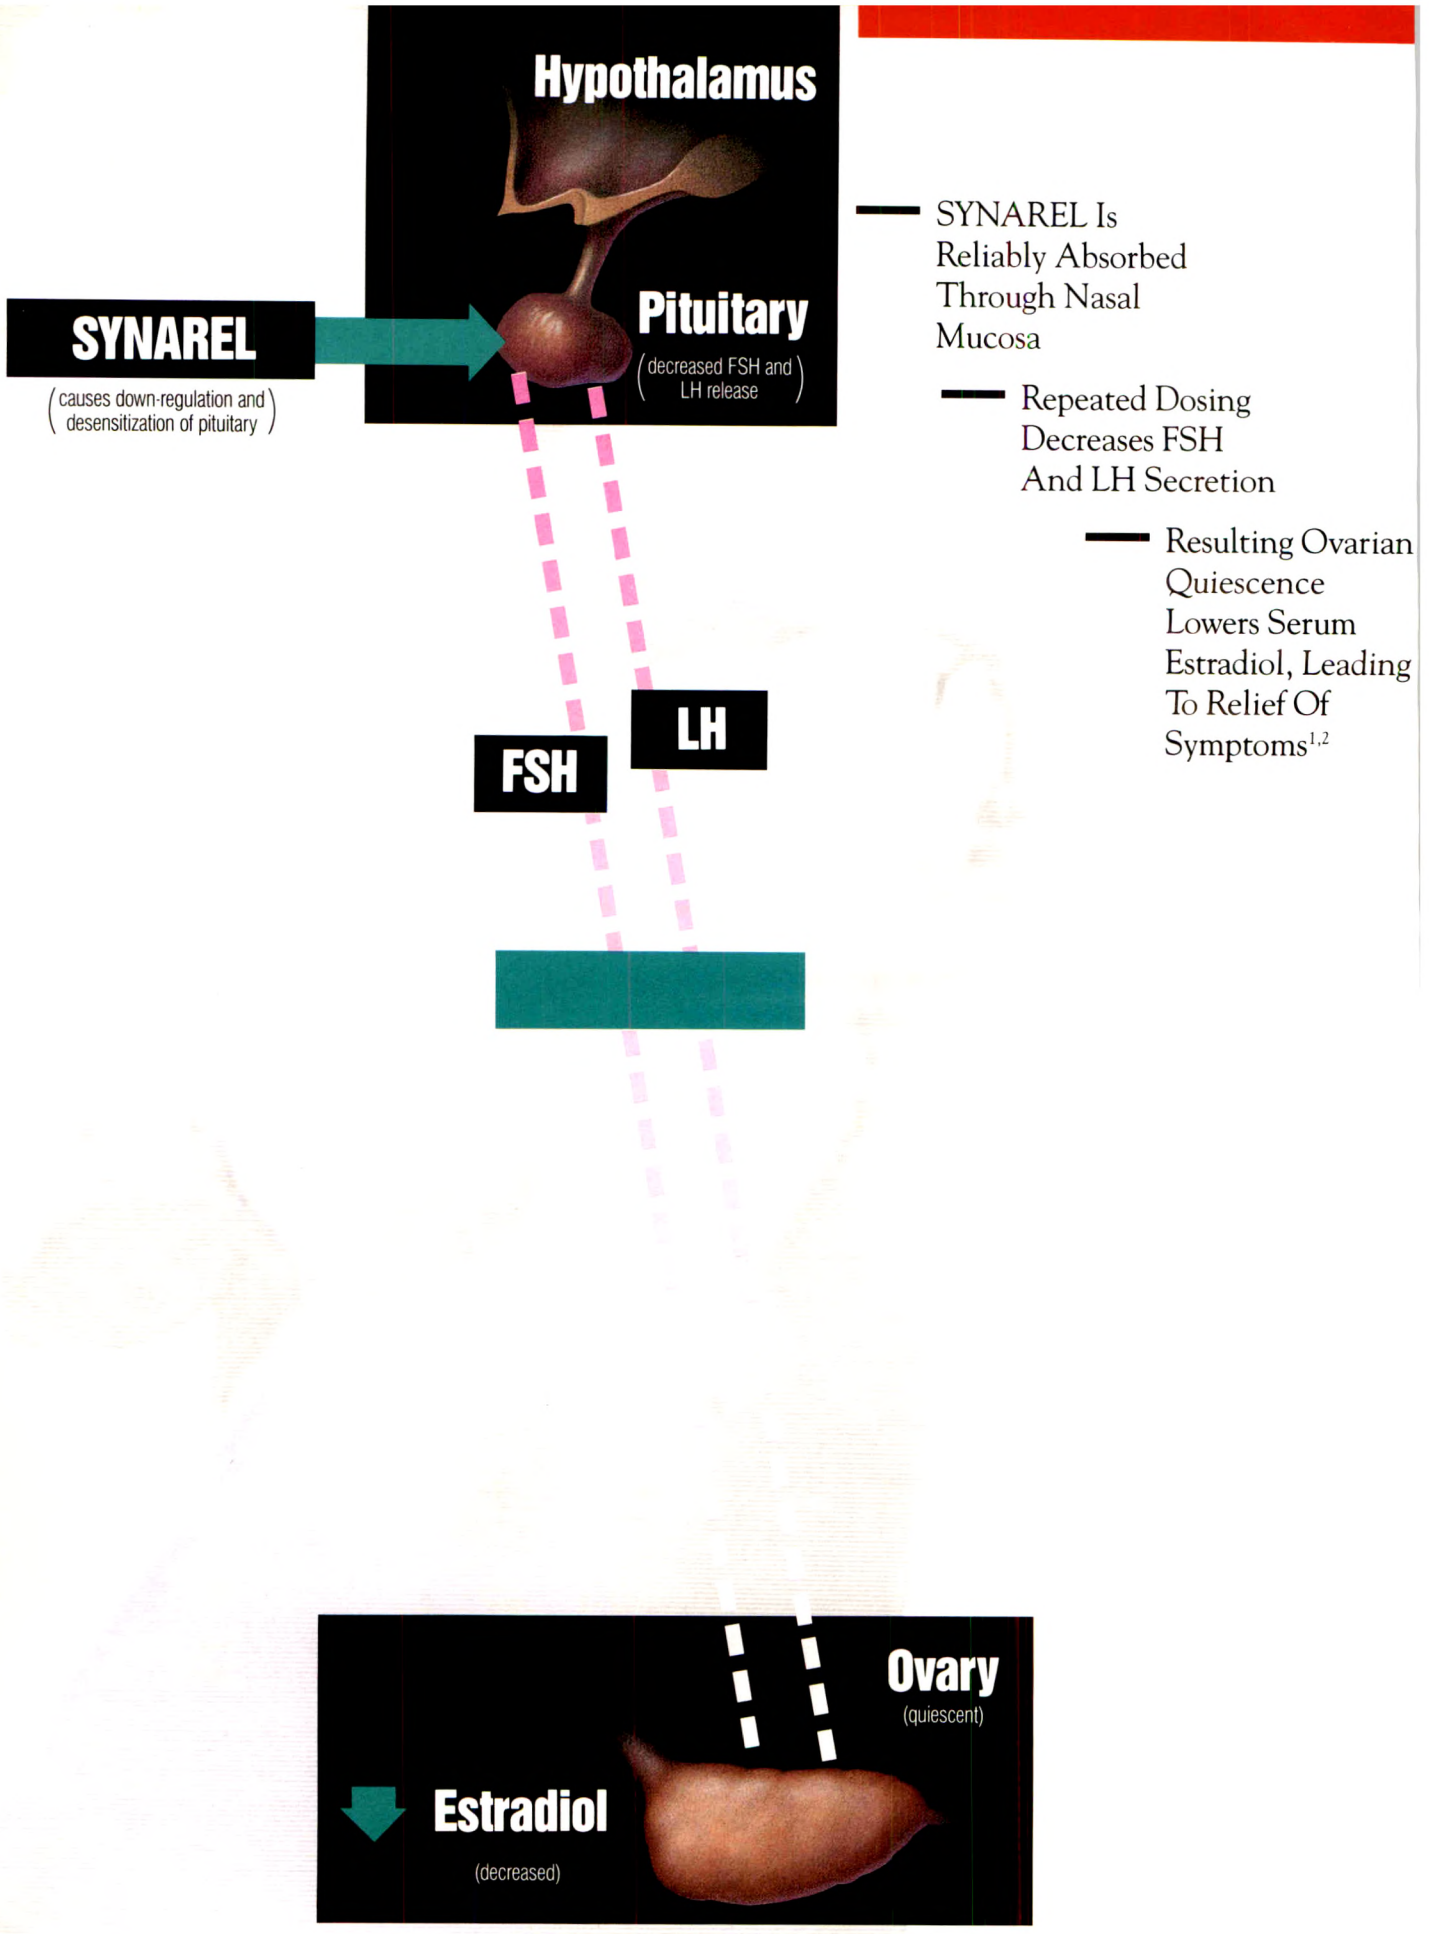
Dr. Young, I am concerned about the comparability of your two groups. Your change of freezing techniques makes the frozen sperm group actually two different groups. Did you do any intrauterine inseminations? It appears that some of your timing of insemination was by basal temperature graphs alone and some by luteinizing hormone surge. Moreover, you changed the minimum required number of sperm per specimen; and in some cases you did two inseminations rather than a single insemination per cycle. Each of these factors could have a profound impact on success rates.

DR. YOUNG (Closing). It is interesting that two centers have been able to obtain permission for studies involving fresh semen. I personally thought that the American Fertility Society acted precipitately in issuing the February 1988 statement saying that fresh semen

should not be used at all. The risk of transmitting acquired immunodeficiency syndrome is very small and can be very carefully controlled. For that matter, no one really knows if a 3- or 6-month quarantine guarantees a specimen free of the human immunodeficiency virus. A prospective randomized clinical trial with fresh and frozen specimens is thus very appropriate.



I believe that in two clinical situations the use of fresh semen is appropriate. (1) Couples who have arranged a woman surrogate for insemination have no wish to use frozen specimens and neither does the surrogate. (2) For the occasional couple who have personally arranged a known donor for one reason or another, I also use fresh semen. I regard these two situations as having the same risks as having intercourse with the semen donor. We have these people sign stacks of waivers and go ahead with fresh inseminations. We do test the donor but we do not require that his specimen be frozen.



We changed our minimum total count for insemination from 12.5 to 20 million when it was technically possible to do so. I would guess that at least half the patients had >20 million per milliliter and the other half had between 12.5 and 20. I'm disappointed that the change from 12.5 to 20 hasn't resulted in a more impressive change in pregnancy rates. I hope that the change will be more dramatic when we can get to 40 or 50 million per milliliter. We did not analyze the effect of the woman's age.

In view of the longer time required to achieve a pregnancy with frozen semen, one may well ask if the evaluation of the woman should be changed. We had routinely done diagnostic studies of women who failed to conceive after 6 months of inseminations with fresh semen. We knew that 70% or so of those who are going to conceive will have done so within that time. When we use frozen sperm, I believe that we should wait until 9 or 12 months, depending on the age of the patient.

I'm not impressed that intrauterine insemination solves many problems. Of course, if you can take a normal specimen, wash it, and get 24 million motile sperm to put in the uterus, I have no doubt that you'll have a very good pregnancy rate. In the infertile couple with a male factor or when one is using frozen specimens, that can't be done. The critical thing for artificial insemination is to improve our technology to get the maximum number of motile sperm for delivery to the cervix. There is nothing mysterious about that. Freezing technologies will improve so that we can do it. We should be able to find the number of motile sperm needed to make the pregnancy rate equal to that with fresh sperm.

Dr. Hanson, we use intrauterine insemination as the next step when cervical insemination has been deemed to fail, that is, after 6, 12, or 18 months, depending on the individual case. We have done only a few cases of intrauterine insemination with frozen sperm and are not impressed. We tend to move on quickly to something else at that point.

New SYNAREL® For Endometriosis
(NAFARELIN ACETATE)

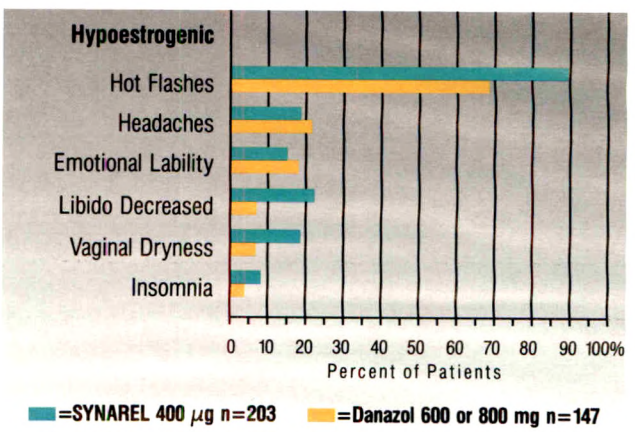
Lowers Estrogen Without Adding Androgens[1, 2]



Synarel Exhibits Fewer Masculinizing Side Effects Than Danazol

Adverse events during 6 months treatment

- More frequent and/or severe with danazol:
  Weight gain
  Edema
  Acne
  Oily skin
  Hirsutism
- Some androgenic effects of danazol—such as voice deepening—may be irreversible[3]
- Patients should be advised to use non-hormonal methods of contraception when taking SYNAREL

Synarel Exhibits Predictable Hypoestrogenic Profile

Adverse events during 6 months treatment

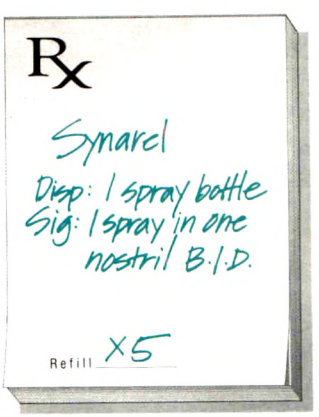
- Estrogen levels return to normal after cessation of therapy
- Bone changes largely reversible 6 months post-treatment

Bone Density Changes During And After Treatment With SYNAREL (400 μg/day)

Site Method Units	Time of Study Baseline	End of Treatment	Post-treatment
Lumbar Vertebrae QCT,* Integral (g/vertebrae) n=21	13.4	12.8 −4.3%	13.1 −3.3%
Trabecular Bone of Vertebrae QCT* (mg/cc) n=23	161.3	147.6 −8.7%	152.0 −4.9%
Lumbar Vertebrae DPA† (g/cm^2) n=6	0.98	0.93 −5.9%	0.96 −1.4%
Distal Radius SPA** (Units) n=6	40.2	39.5 −1.6%	39.6 −0.8%

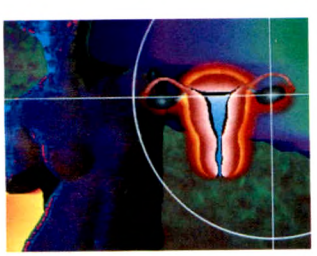
Percent changes from baseline

*Quantitative computed tomography
†Dual photon absorptiometry
**Single photon absorptiometry



Intranasal Administration

Synarel Is The Only GnRH* Agonist Administered Intranasally



B.I.D. controlled-dose administration offers:

- Highly accurate metered-dose delivery—200 µg/spray
- Reliable absorption through nasal mucosa
- Patient convenience with low incidence of nasal irritation (10%)

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrough bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4–8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4–8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 4.3% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

The computerized digital imaging colposcope: Future directions

William E. Crisp, MD,[a] Brian L. Craine, MD, PhD,[b] and Eric A. Craine, PhD[c]

Phoenix and Tucson, Arizona, Oakland, California, and Ft. Collins, Colorado

A computer-aided colposcope has been developed for enhancement and analysis of colposcopic images. There are numerous possible applications of this system, including image archiving, image enhancement and processing, and quantitative measurements of various features in the images. In addition, a wide range of digital filters can be applied to the system that may be used to detail different aspects of the image. The method for a new mode of applying digital and optical filters to the colposcope is discussed and future directions for the system are suggested. (AM J OBSTET GYNECOL 1990;162:1491-8.)

Key words: Colposcopy, computer imaging, image processing

Although the colposcopic evaluation of the female lower genital tract has been well established, the basic optical system of the colposcope has not changed since it was introduced by Hinselmann in 1925.[1] A brief historic outline of major developments related to colposcopy is shown in Table I. The static state of the present colposcope has limited its use to primary diagnosis of the abnormal Papanicolaou smear as a single event.

The potential scope of the "abnormal Papanicolaou smear" problem is enormous. Ten percent of sexually active Americans, approximately four million people, harbor the human papilloma virus (HPV). There are more than one million new cases of genital warts each year. There are now 57 varieties of HPV; most types are relatively harmless, but types 16 and 18 are carcinogenic.[2, 3]

The HPV problem necessitated that a new clinical approach was mandatory if the pathogenesis of these lesions was to be studied further. A system for computerized, enhanced image analysis, viewed and measured through a range of light sources, offers the possibility of a technique to improve our understanding of the cervical HPV lesion. This type of system was developed by Craine et al.[4]; similar techniques have since been used by other groups.[5]

In this article we discuss some of the basics of the system, indicate the nature of some of the experiments we are doing, and discuss some possible advantages that may emerge from use of the digital imaging techniques.

Table I. Milestones in the development of colposcopic diagnosis and treatment of cervical intraepithelial neoplasia

Year	*Development*
1924	Hinselman fixed a light source to a dissecting microscope (×3.5 magnification)
1925	Hinselman built the first colposcope, described surface carcinoma (cervical intraepithelial neoplasia)
1930	Introduction of the colpomicroscope
1940	Papanicolaou smear, thought to be competitive with the colposcope
1960	Cryosurgery introduced
1980	Laser surgery introduced
1988	Introduction of the first computer-aided colposcope

Material and methods

The digital imaging colposcope that we use is the DENCOL 2100, a prototype of which was described by Craine et al.[4] This system consists of a stock Zeiss photocolposcope (Carl Zeiss Inc., Thornwood, N.Y.) to which is attached an optical interface and a video format, solid state, two-dimensional charge-coupled device imager. The incoming image is transferred to the charge-coupled device by means of an optical beam-splitter in the colposcope and, with proper adjustment of the transfer optics, the scene viewed through the binocular eyepiece is identically transferred to the charge-coupled device. The chargecoupled device is a silicone-based device that offers a broad range of spectral response from the ultraviolet cutoff to the optical infrared.

An RS-170 format video signal is carried through a

5 to 7 meter long coaxial cable to a digitizing board set residing in a host 80286 architecture microcomputer. The board set is a dual-frame buffer design that allows two digital images to be instantly available at all times for processing. The incoming video images are digitized at a spatial resolution of 512 × 480 px and a contrast resolution of 7 or 8 bits, depending on whether a graphics overlay plane is activated.

The host microcomputer supports a computer monitor (through a Hercules graphics card or its equivalent) and a video monitor; it is interfaced by a keyboard and a mouse. A 20 Mb hard disk provides nonarchival storage and a high-density (1.2 Mb) diskette drive is used for moving images to archival locations.

In addition to a variety of digital filters, discussed briefly below, it is thought that some advantage may be derived from use of multispectral optical filters in the system. We have initiated some preliminary experiments to address this issue and will discuss some aspects of those experiments in this article.

The system is completed by an application specific software package (COLPO) in a menu-driven format. This package allows a range of file manipulation functions, and some modest image processing and analysis functions. Experiments are underway to determine the most satisfactory form factors for the system and to explore a variety of image processing algorithms that might be most useful for clinical colposcopy applications.

The COLPO main menu currently consists of five basic menus: File, Acquire, View, Enhance, and Analyze.

The *File* menu enables the user to load, save, copy, rename, or delete images. In addition the user may elect this option to display an image directory or to quit the program.

The *Acquire* menu is selected if the user wants to digitize a live input image into either of the two onboard memory locations, or pages.

The *View* menu allows the user to display the current live image, or either of the two digitized images currently in the dual-frame buffers. An additional useful feature is that any set of images (live or digital) may be sequentially displayed on the video monitor at a user-selected frequency. The result is a video "blink comparator" system that rapidly and dramatically displays differences between similar, but perhaps subtly different, images (such as a series of images obtained in the course of monitoring a patient over a period of time). The *View* menu also allows the user to display or hide the graphics overlay plane.

The *Enhance* menu offers contrast enhancement control over the displayed image (either real-time live examination images or stored digital images), as well as a selection of 3 × 3 digital filters that can enhance contrast gradients or feature edges (such as boundaries to areas of dysplasia) or high-frequency features (such as blood vessels or punctation).

The *Analyze* menu allows use of a graphics overlay plane to calibrate and measure distances, perimeters, and areas of features of interest in the image. The user may also use this menu to annotate the image with text or symbols.

Our experimental software system has incorporated capabilities to add, subtract, and divide the digital images as well as apply additional digital filters to the colposcope images. These functions allow the user to extract subtle features of interest by reducing noise in the images, or by removing an unwanted background that may be cluttered or otherwise confusing in interpretation of the image. These functions may be particularly useful in combination with various digital and optical filters.

The conventional method for digital image capture with this system is as follows. The desired magnification for viewing is selected at the colposcope and a glass optical filter, if needed, is inserted in the outgoing light path (i.e., in the fiber optic illumination system). The scene of interest is selected either by visual observation through the colposcope or by monitoring the video display. At this point the user may elect to turn on the contrast enhancement and probe the dynamic range of the current live image. In any event, when a satisfactory image is displayed it may be digitized in a fraction of a second by a keystroke.

The digital image is then displayed and, if not satisfactory for any reason, is simply written over by a new digitized image. The whole process requires less than a second and can be iterated in any manner. The digital image may then be processed and studied, or it may be moved to the next lower level of storage, the hard disk.

There is a variation on this method of digital image capture that is potentially very useful. It is sometimes desirable to capture two or more digital images that are, as nearly as possible, exactly registered in terms of scale, rotation, and translation (i.e., the images precisely overlay one another). This situation could arise, for example, if one wanted to perform the aforementioned blink comparison of images obtained at different times. Similarly, if certain processing operations involving the subtraction of one image from another, or the division of one image by another, are to be performed, registration of the images would be necessary.

In this case the procedure is as follows. When the desired scene is displayed in the live video format it is digitized into one image buffer (for example page 1); the second scene is then established on the live video and the two images, page 1 and input video, are sequentially displayed at moderately high frequency with

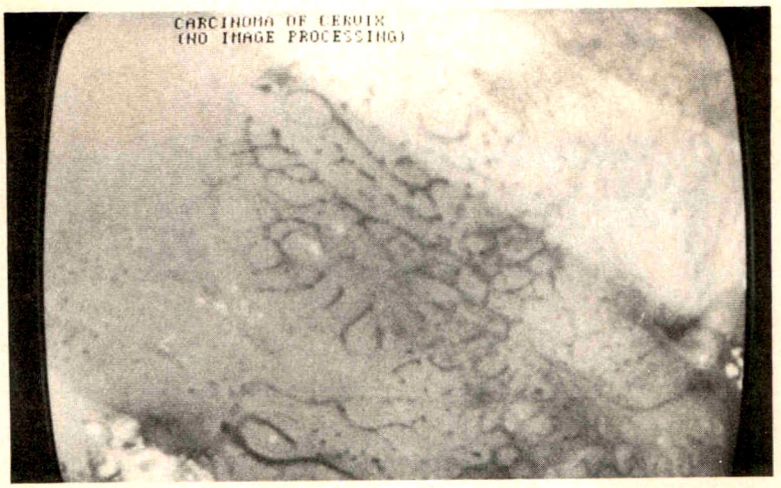

Fig. 1. Unprocessed image of cervix showing mosaicism surrounding the os.

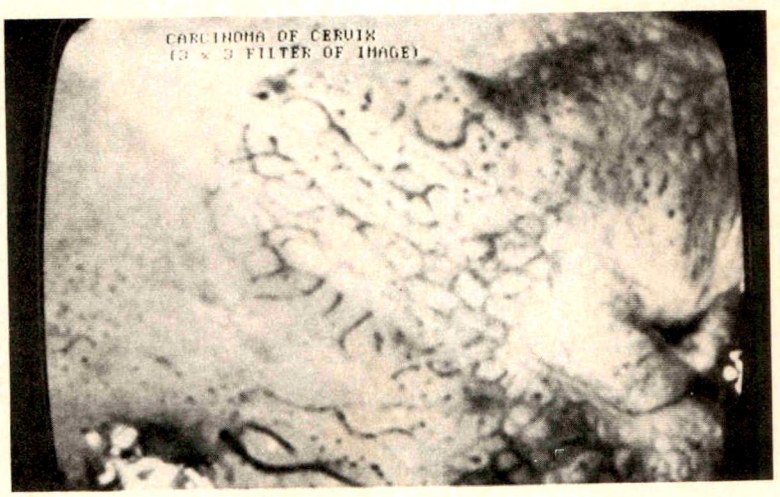

Fig. 2. The image of Fig. 1 processed by a pixel by pixel operation using a 3 × 3 digital filter convolution.

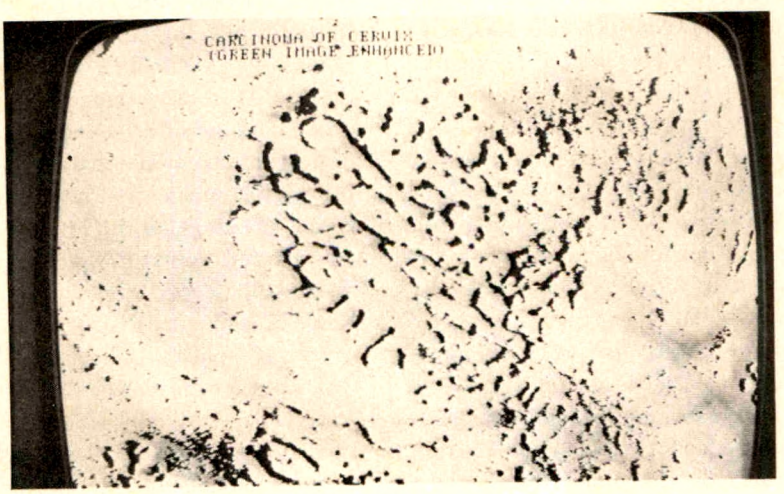

Fig. 3. The image of Fig. 1 showing enhancement of vasculature features with a digital filter operation comparing images obtained in white light and a monochromatic green band optical filter.

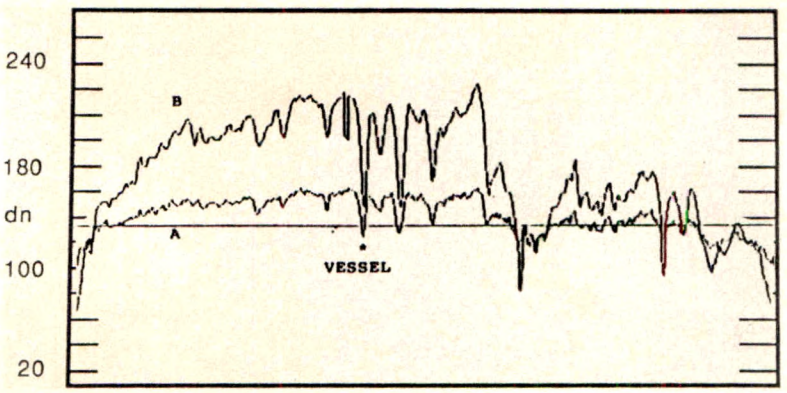

Fig. 4. A line plot across line 116 of the images in Figs. 1 and 2; *dn* is the data number value of the pixel. *Line A* is from the image before any processing; *line B* is from the same region after a 3 × 3 filter convolution process. The *asterisk* denotes a region of increased density corresponding to a blood vessel. Note the increased size of this peak relative to the background and the general decrease in intensity of the image (higher pixel values correspond to a whiter image).

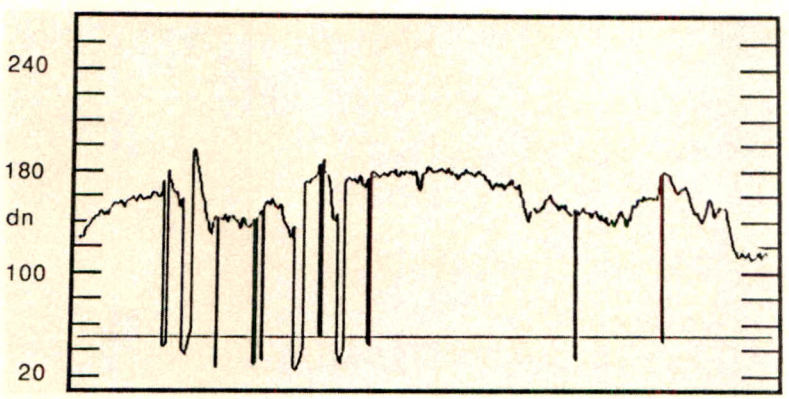

Fig. 5. Line plot through line 388 of the enhanced image shown in Fig. 1 with a pixel error of 15.

the blink comparison capability. Any errors in registration between the two images are readily apparent and easily corrected by moving the colposcope, thus changing the orientation of the live input image. When satisfactory registration between the two scenes is achieved the input image is then digitized as page 2. One possible use of this capability is to place an archived image from an earlier examination in page 1 and use the live image from the current examination as the second image for comparison.

For our current purposes we are interested in use of this capability to compare images obtained during the same examination but using different filtering operations during the examination.

From the standpoint of optical filter use, it is important to recall that light may be described as a wave phenomenon in which the nature of the light is defined by an amplitude and wavelength. Colposcopic examinations are often conducted with white light, which is the sum of electromagnetic energies over the range of wavelengths to which the eye is sensitive, typically blue at short wavelengths to red at longer wavelengths.

Specific colors, or narrow wavelength bands, of light may interact differently with different biologic tissues based on the energy in the light and the nature of the tissue. This phenomenon has been used to advantage in colposcopy, for example, by introduction of a green optical filter to enhance the contrast of blood vessels in the cervix. In fact, numerous filter combinations over a broad range of wavelengths could be implemented to provide potential enhancement of various tissues in colposcopic images. An interesting possibility involves taking advantage of the broad wavelength response of the charge-coupled device detector in the digital imaging colposcope, which has a significantly greater range of sensitivity than the human eye.

To accomplish this, we have begun experimentation with several different modes of filtering digital colposcopic images. These experiments include the use of (1) digital filters in the host computer, (2) optical filters in the colposcope optical path, and (3) combinations of both. In the following section we outline some examples of this type of work and suggest benefits and directions for future efforts.

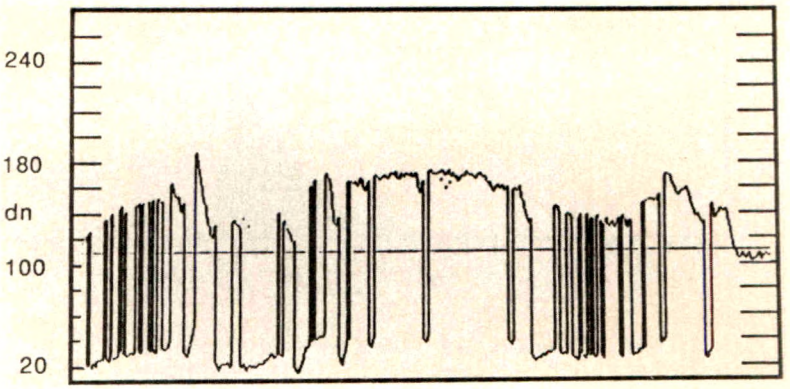

Fig. 6. The same as Fig. 5 but for a pixel error of 5 gray levels.

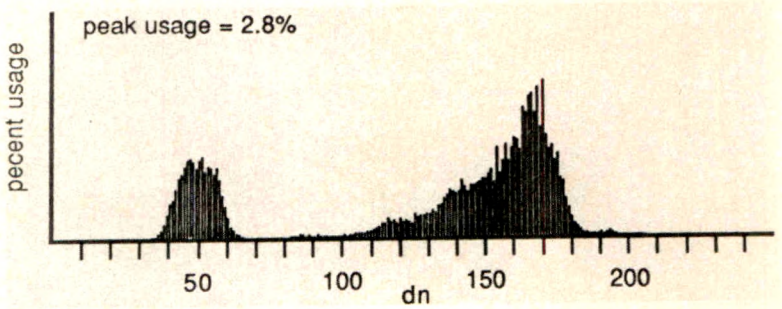

Fig. 7. The image histogram of the image produced by computer enhancement techniques described for Fig. 3; the pixel error threshold was set at 15 gray levels.

Results

One of the primary goals of the processing of colposcopic images is to accentuate the pattern of blood vessels of the cervix that is a feature diagnostic of cervical neoplasia. Two methods that are particulary useful and can be implemented on a microcomputer are the use of 3 × 3 digital filters, and the comparison of images digitized with and without green light illumination. The latter method is unique to colposcopy and the subject of a proprietary software algorithm of Western Reseach Company, Inc.

The 3 × 3 filtering of the image can be accomplished in about 10 seconds with software written in the C language. This is an adequate time but can be further accelerated by including machine language subroutines. The 3 × 3 filtering can produce excellent enhancement of visualization of the blood vessels. The background is deemphasized and the vessels are enhanced (for example, see Figs. 1 to 3). Fig. 4 shows a line plot through a region of vessels before and after filtering. The vessel feature is clearly emphasized; the area under the peak corresponding to the vessel is obviously greater in the filtered image while the baseline is greatly reduced.

A common feature of colposcopes is the presence of a green filter through which to observe the cervix. This light filtering system increases the contrast of the vessels although decreasing the overall light intensity of the image. We have designed an image processing algorithm to take advantage of the ability to obtain images with the green filter. This involves a pixel by pixel comparison of the green filter image with the normal white light image. Those pixels that are accentuated with the green filter are multiplied by a factor to emphasize those pixels. Since the entire green-filtered image has decreased intensity, compared with the white light image, it is necessary to correct for the average intensity of the images. The ability to differentiate features also depends on the average variance of individual pixel values. To correct for this problem it is necessary to determine the optimal difference between pixel values before a determination is made that the feature is truly darker in the green-filtered image.

The effect of setting the allowable variance in pixel values can be seen graphically in Figs. 5 and 6 that show line plots at the same level of the colpophotograph with different minimal intensity pixel difference criteria of 15 and 5 gray levels. The effect of increasing the criteria is to reduce noise because of random areas in which the green-filtered image is more intense than that of the white light–illuminated sample. This noise is seen as the sharp spikes. The specific areas of vessels are accentuated and are seen as smoother, broader regions of enhanced intensity. The effect can also be seen in

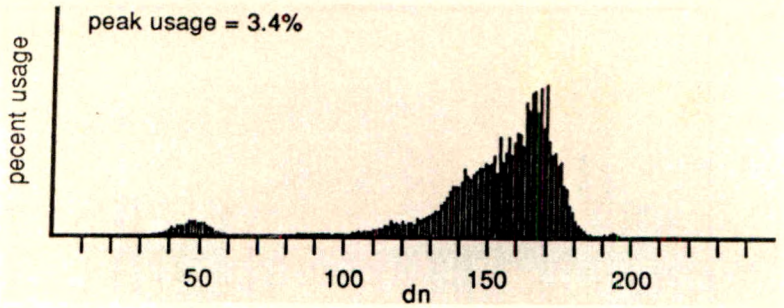

Fig. 8. The same as Fig. 7 but for the data in Fig. 6.

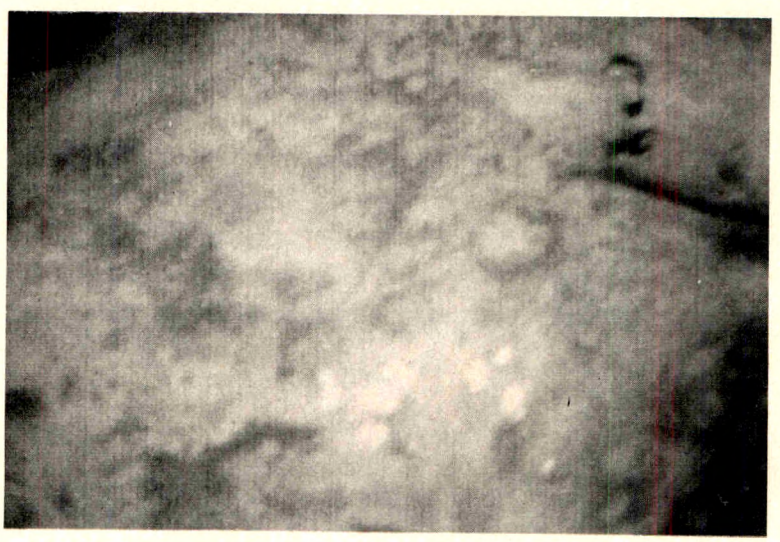

Fig. 9. A segment of an unfiltered colposcopic image obtained with the digital imaging colposcope.

the histograms of the entire image as shown in Figs. 7 and 8. The pixels corresponding to blood vessels are well separated as a new peak in the image histogram. With increasing stringency this peak is decreased in area as it becomes more specfific.

The result of this form of image processing can be seen most dramatically in Fig. 3, which is a photograph of the CRT display of the 256 gray level image of a colpophotograph of a cervical carcinoma. Compared with Fig. 1 there is a dramatic increase in intensity of the vessels. This type of enhancement may prove particulary useful in the development of algorithms for automatic extraction of vascular features in colposcopic images.

Another approach to filtering of colposcopic images that may offer benefits in understanding the nature and condition of the tissue under examination is the use of multispectral imaging. The concept here, the same as is widely used in remote sensing, involves imaging the same area of the cervix in light that is limited by two or more different wavelength bandpasses (i.e., different colors). The resulting images must be exactly registered, as described in the method discussion, and the resulting multispectral images may then be subtracted from one another, or one may be divided by the other. The result is the selective enhancement of features that respond differently to the specific wavelengths of light used. A more detailed discussion of elements of color and multispectral colposcopic imaging may be found in Craine et al.[6] and Craine et al.[7]

In our preliminary experiments we have worked with broadband filters isolating violet, green, yellow, orange, and red light. The images in each band have been registered and various combinations of subtracting and dividing the images have been tested. An example of a segment of an unfiltered image is shown in Fig. 9; the green image divided by the corresponding red image is shown in Fig. 10. It is apparent that selective contrast enhancement has taken place and that portions of the tissue have been emphasized.

Comment

The computerized digital imaging colposcope allows for storage of the image, serial observations and analysis of the lesion, accurate measurement of the lesion, enhancement and manipulation of the digital image, and the use of a variety of optical filters to create new, potentially useful versions of the image. The enhanced

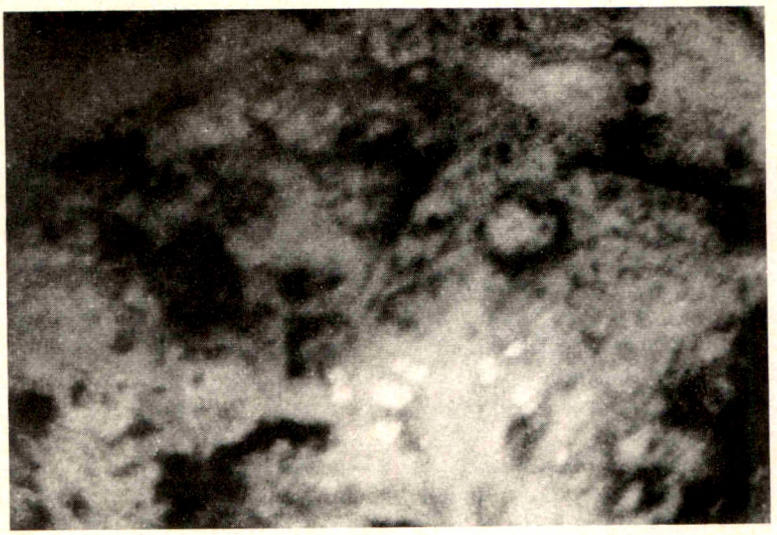

Fig. 10. The same scene as in Fig. 9 but resulting from the division of the green filtered image by the corresponding red image.

colposcopic image, analyzed with any or all of the aforementioned options, then becomes useful as a research tool to fully assess the surface structure of the uterine cervix.

In addition to the generally recognized advantages of digital imaging, the digital imaging colposcope we have described offers a number of novel features that make it attractive for use in a variety of research programs; many of these features may eventually prove to be clinically useful.

The preliminary work we report here clearly indicates that we can accomplish the following: (1) colposcopic images can be enhanced with digital filters as well as the traditional green optical filter, (2) multiple colposcopic images can be registered using the dual-frame buffer capability of the system, and, (3) multispectral colposcopic images can quickly and easily be compared with image subtract and divide functions.

Our plan is to use these capabilities to build a substantial database of digital colposcopic images that represent a range of heretofore unobtainable colposcopic views of the cervix. These images will be analyzed in the context of histopathology with a goal being the development of a potentially new, dynamic colposcopic methodology.

We appreciate the cooperation and assistance of Samaritan Medical Center of Phoenix, Arizona in ongoing research on this methodology. Valuable assistance was provided by Dr. John R. Engel and Neil T. Wemple.

Discussion

Dr. Edward C. Hill, San Francisco, California. Last month we were privileged to view the surface of the planet, Neptune, by way of computer-enhanced images transmitted from a video camera two billion miles away. This month, in a similar fashion, we are given the opportunity to study a surface much more familiar to us, the cervical mucosa, seen through the colposcope and transmitted to a microcomputer via a cable 5 to 7 meters long. Although the significance of the information transmitted back to earth from the satellite *Voyager II* has been pronounced by space experts as equal to that of the discovery of America by Christopher Columbus, we do not yet know where this novel use of a computerized digital imaging colposcope will lead. Dr. Crisp and his coworkers in this endeavor, Drs. Brian and Eric Craine, have followed the lead of a number of Italian investigators in combining the colposcope with computer graphics. This is only a milestone on the road of attempts to enhance colposcopic images. Dr. Crisp mentioned that the basic optical system of the colposcope has not changed since it was introduced by Hinselmann in 1925. Actually, there have been improvements in

illumination, magnification, and lengthening of the focal distance from 12 to 20 cm. In 1938, Hinselmann described the effect of dilute acetic acid on the appearance of the mucosa, enhancing the visualization of columnar epithelium, transformation zones, and atypical epithelium. The introduction of the green filter by Kraatz in 1939 was a great step forward because it facilitated the visualization under white light of the vascular pattern of the mucosa.

The problem of properly recording colposcopic observations was recognized very early, and it was soon acknowledged that this could be accomplished only through colpophotography. Both color and black-and-white photography have been used, and each has its advantages and disadvantages. In my discussion I would like to pay tribute to the contributions of two Norwegian pioneers of this method, Dr. Odmund Koller, and his successor, Dr. Per Kolstad, of the Norwegian Radium Hospital in Oslo, who have used black-and-white photography to great advantage in advancing our knowledge of the microangioarchitecture of the cervix in health and in disease. Their technique certainly was one of the most significant in the various attempts over the years to enhance and record colposcopic images, the subject of this article.

Twenty-five years ago, while spending part of a sabbatical year in Stockholm, Sweden, I met a young Norwegian gynecologist, Dr. Kolstad, who at that time was pursuing his work in colposcopy at the Karolinska Institute. He used a technique of colpophotography developed by Dr. Koller. To my knowledge, this method was the first attempt to show, record, classify and correlate the vascular patterns of the cervix with various clinical entities, particulary those associated with neoplasia. The method involved a high-resolution optical and photography system, using ultrafine grain black-and-white film with orthochromatic sensitivity, strong illumination, and a high magnification. These were achieved by shortening the focal length to 12.5 cm (rather than the 20 to 30 cm length used in routine colposcopy); this required a special vaginal speculum. The magnification objective on the Zeiss colposcope was set at $\times 16$, and the camera lens aperture at f/32. This combination resulted in a resolved distance of 15 μm and a depth of field of 0.8 mm. To obtain complete pictures of the entire portio vaginalis, up to 30 exposures were made. These were then enlarged five times, the best prints were selected and arranged into composite pictures mounted on poster board.

The advent of portable television cameras allowed the attachment of these recording devices to the colposcope, and with the adaptation of the television monitor to the computer, it was inevitable that there would eventually be a marriage between the colposcope and computer graphics. But is this just another example of technology looking for an application? Contini and his coworkers in Milan have already published their work in this area in the March 1989 issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY (see the authors' ref. 5), describing it as a new method that may be useful not only for documentation but as a research tool. It is fascinating to see what the authors have been able to accomplish in enhancing various colposcopic findings through digital manipulation of the images. Because of the price tag of about $25,000 in addition to the cost of the colposcope, it is highly unlikely that the average gynecologist will acquire one. Speaking from a position of having tried over a period of several years in the 1960s to follow the natural history of cervical dysplasia with a combination of cytology and colpophotography, I can readily appreciate the facility that this method allows. It has the advantages of the ability to correct recording techniques "on the spot," of the enhancement features that are available, and most importantly, of the ability to store, retrieve, and compare images over time. With the use of a modem, colposcopic images can be transmitted via telephone lines cross country or even abroad. Clearly this new method is worth pursuing.

DR. CRISP (Closing). Thank you, Dr. Hill, for your comments. I visited Dr. Contini's clinic in Milan 2 years ago and was aware of their recently published data utilizing the computer to store and compare colposcopic images. Our instrument adds, for the first time, the ability to use light filters from four different color sources to provide combinations of lights of different wavelengths. We lack any real knowledge of which tissues best absorb which type(s) of light. Light is an electromagnetic force that varies in amplitude and in wavelength from red to blue. It is my impression that different disease states of the cervix absorb different colors of light. Therefore this extension of the use of a green filter that we have discussed will add to the clinician's ability to categorize cervical lesions in the range from benign to malignant.

The application of computer technology gives the colposcope a new dynamic ability to apply different combinations of light filters to the study of cervical neoplasia. This use of various types and combinations of light energy will hasten the development of photobiology.

TRANSACTIONS OF THE FIFTY-SEVENTH ANNUAL MEETING OF THE CENTRAL ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Men without chests

Presidential address

James H. Maxwell, MD
Colorado Springs, Colorado

In coming before the body of the Central Association of Obstetricians and Gynecologists this morning, I am discharging the most difficult of the responsibilities that are charged to the president of the organization, that of addressing the Association about some matter that is important in our field, and of doing that with integrity and sensitivity. The subject I have chosen to speak about has to do with decision making. As I hope will be clear as the speech unfolds, I consider actions derived from decision making the most important single problem facing the body of medicine in the United States today. The magnitude of the problem is definitely not limited to the practice of medicine, but I will confine my remarks to that field.

Until quite modern times, almost all persons believed the universe to be such that there was a congruence of our nature, our feelings, and the universe wherein we live. An excellent example of this congruence is expressed in the second paragraph of the Declaration of Independence of the United States of America, where it is stated, "We hold these truths to be self-evident that all men are created equal, that they are endowed by their creator with certain unalienable rights. Among these are life, liberty, and the pursuit of happiness. . . ."

In the early years of the last century, with the introduction of Hegel's system of philosophy, which incorporates the thesis-antithesis-synthesis concept, relativism was born. The fruit of relativism is a general philosophic theory that all values are subjective and trivial. In our day this has worked out by the fluidity of the law, with the interpretation and the reinterpretation of the Constitution, to mean whatever the *zeitgeist* or spirit of the time deems it to be. The judges of ancient Israel expressed the same thought, "Every man did what was right in his own eyes." There was no rock-solid standard applied and behavior flowed up or down as the moral climate of each day dictated.

Even Hegel and his pupils recognized the need of some "absolute" or ultimate source of authority, and he determined that the state held ultimate authority. The world of our fathers and ourselves has suffered through two great world wars and their aftermaths, the awful holocaust, and Vietnam because Hegel taught that the *state* was the ultimate arbiter of values. Marx used Hegelian philosophy as the value basis of communism. Hitler took Hegel through Nietzsche and formed the concept of the super race; thereby these two have subjected the modern world to the most terrible brutality known to mankind.

Unfortunately, these same concepts of relativism have essentially totally infiltrated the fields of the social sciences and the field of education. For confirmation, meditate on what Alan Bloom was really saying in *The Closing of the American Mind.*

Much was made in the early days of the twentieth century of Einstein's theory of general relativity in which a direct relationship between mass and energy was postulated. The idea of relativity was quickly (and erroneously) applied to a relativistic value system and was deemed to have scientifically proved at most, and supported at least, the relativistic position of the social and political scientists. Lost to the eyes of the relativistic position was the powerful fact that the relationship of mass and energy, expressed in the general theory of relativity, was bound by the strongest of all absolutes in the physical world—the speed of light—

unchanging, unalterable, solid as a rock, not changing with the mood of the current leading physicists.[1]

Now what does all of the foregoing have to do with obstetricians and gynecologists in the Central Association? Much, I do believe. This past spring a great festival was held in Denver to honor one of our own—Tommy Evans, emeritus professor at Colorado University and former president of both the Central Association and the American College of Obstetricians and Gynecologists.

The most enthusiastic participants in this festschrift for Tommy were many of his former students. Why were they there? To honor *The Professor.* What had The Professor taught them? Lots of facts about our discipline; when to induce labor and when not to, the best therapy for endometriosis, an effective algorithm for the management of infertility, and on and on. But in talking with many of the students, some of whom are now professors in their own right, what The Professor had taught them was an approach to decision making.

To make good obstetric and gynecologic decisions requires the application of good science and good ethics to a problem. All of us realize that science changes as learning unfolds. For example, many of us in this audience learned in our generation in our genetic course in college that there were 48 human chromosomes. Now all of this has changed, and molecular biology is delving deeply into the very life processes. The entire process of continuing medical education, which is the very cause for the existence of the Central, as well as the peer-review medical journals, is dedicated to supplying the latest and best of science and learning.

But what of the ethics? To mire ethics in the morass of relativism completely strips our values of any firm basis for excellence. Ethics requires "the constant," just as much as the general theory of relativity required "the constant." The denial of this need for "the constant" subjects humanity to the control of either the trousered apes who make all decisions by visceral reaction, or to the cerebral guides who place no value on any other than that which their minds conceive. Our need is for men with chests—decision makers who integrate visceral response and cerebral acumen with "heart," ethics that do not fluctuate with the whim or need of the moment, integration of right and courage.[2]

Values that are based on "the constant," and behavior that is derived from these values is good and right. It is right not because someone forces it on us, but rather, it stands as right on its own. It is right because it fits. It is right because it is congruent with "the constant." When we have a value system based on relativism, questions arise in the minds of everyone, such as, does that mean that we can decide for ourselves if we will be honest or not? Is it better to tell a lie when it appears to be in our best interest rather than to always be honest? The same kind of ethical quagmire exists when one looks at any question of behavior from a relativistic viewpoint. One of the great ironies of our day is, that we laud the value. We say "honesty is the best policy," but our behavior teaches the learner the exact opposite. The learner sees, in relativistic behavior, a self-seeking value as the only value; and this of course leads to moral anarchy. As C. S. Lewis said, "We continue to clamor for those very qualities we are rendering impossible . . . we make men without chests and expect of them virtue and enterprise. We laugh at honor and are shocked to find traitors in our midst. We castrate and bid the geldings be fruitful."[3]

Is this a new idea? Not at all. Aristotle taught that the aim of education is to make the pupil like and dislike what he ought.[4] In *The Republic* Plato stated that the well-nurtured youth is one "who would see most clearly whatever was amiss in ill-made works of man or ill-grown works of nature, and with a just distaste would blame and hate the ugly even from his earliest years and would give delighted praise to beauty, receiving it into his soul and being nourished by it so that he becomes a man of gentle heart. All this before he is of an age to reason; so that when reason, at length, comes to him, then, bred as he has been, he will hold out his hands and welcome and recognize her because of the affinity he bears to her."[5] In early Hinduism, that conduct in man that can be called good consists in conformity with or almost participation in the *Rta*—that great ritual or pattern of nature and supernature that is revealed alike in the cosmic order, the moral virtues, and the ceremonial of the temple. Righteousness, correctness, order—the *Rta*—is constantly identified with sayta or truth, correspondence with reality.[5]

The Chinese also speak of a great thing (the greatest thing) called the Tao. It is the reality beyond all predicates, the abyss that was before the creator himself. It is nature. It is the way. The road. It is the way in which the universe goes on. The way in which things everlastingly emerge, stilly and tranquilly, into space and time. It is also the way in which every man should tread in imitation of that cosmic and supercosmic progression, conforming all activities to that great example. "In ritual," say the Chinese, "it is harmony with nature that is prized."[6]

Likewise, the ancient Jewish tradition praised the law as being "true." The Indian sources emphasize truth as "correspondence," whereas the Judaic emphasis is rather on the reliability or trustworthiness of the truth. Faithfulness and permanence are other orders that could be alternative renderings. Truth is that which does not deceive, which does not give, which does not change. It holds water.[7]

There obviously are many differences in these various cultural backgrounds, but all that which is common

with that which is within the Tao is something we should not neglect. It is the doctrine of objective value, the belief that certain attitudes are really true and others are really false to the kind of things the universe is and the kind of things we are. Such a philosophy of life demands a response from us that is congruent, that is, in harmony with this world view.

All of us have watched as young practitioners of our art have come on the scene. We have observed some of true integrity, and we have also observed some whose decisions have been truly the decisions of trousered apes, being driven only by avarice or personal gain. This is not limited to our younger colleagues. We have seen more mature practitioners stumble when faced with moral dilemma. The problems of identifying and detecting those who practice such deception is indeed a difficult one, fraught with many problems in our litigious society. But that should be no obstacle or deterrent to the profession identifying and culling out those who are not worthy of the almost sacred charge of the health and care, not only of women, but of the next generation—the unborn.

Obviously, a heavy responsibility falls on the shoulders of the professors. They are the ones who are in contact with the physicians in training, both at the doctoral level and at the specialty-training level. These persons need great wisdom and great support in the task they face of training, not only in the field of the science, which in a sense is the easy part, but also in the field of the ethic. It would be far better were all candidates for the doctoral degree to be fully screened and fully evaluated and all be of high ethical and moral practice; however, we would be naive to perceive the reality of the situation thusly. Therefore, it is incumbent on the members of the profession as a whole to formulate strategy for the detection and self-discipline of unethical behavior.

It is totally unrealistic to put the burden of moral behavior totally on the shoulders of the professor. It is incumbent on all persons who bear the name of obstetrician and gynecologist to look out for the welfare of our patients. First, foremost, and essentially exclusively, we must back and support the professor in the initial processes of both teaching and weeding out. But we also, in our day-to-day exposure to our colleagues and to the rest of the health care team, must practice and expect of our peers, ethical behavior of the highest order. We cannot expect ethical behavior based on "the constant" from our peers and practice relativistic ethics ourselves. This indeed would be nothing short of castrating the stallion and bidding the gelding be fruitful. The relativist who expunges "the constant," who lives without the Tao, has indeed produced an ethical system that is totally devoid of any life force.

The goal of this idea is not good ethics per se, but rather, good ethical behavior. One of the saddest features of human existence is the disparity between what one thinks he believes, or what one states he believes, and what one actually does believe. The mark of the man who is truly within the Tao, the mark of the man of true integrity, the mark of the man who is in congruence with his belief is the behavior of such a man when such behavior does not appear to be in his "best interests" but is in harmony with his ethics. This man is no trousered ape, responding only to the basest of human drives, nor is this man the cerebral leader who has no comprehension of or sensitivity to his fellow man. Rather, this is the man of integrated personality and character. This indeed is a man with a chest, a person who has a basis in objective reality for decision making, a man with the courage to apply that objective reality to his own life and to the most difficult of situations that he faces day by day in his pursuit of the goal of excellence in the care of women and their unborn. This then is a call to dedicate ourselves to this goal. Let us not be "men without chests."

A prospective controlled study of outcome after trauma during pregnancy

Mark D. Pearlman, MD,[a] Judith E. Tintinalli, MD,[b] and Robert P. Lorenz, MD[a, c]
Royal Oak and Detroit, Michigan

In a prospective cohort study, 85 women who suffered varying degrees of trauma during pregnancy (12 to 41 weeks) were compared with a control group of pregnant women matched for gestational age. Fetomaternal transfusion occurred significantly more frequently in the study group (30.6% vs 8.2%, $p < 0.05$). Study subjects whose placentas were anteriorly placed were at increased risk for fetomaternal transfusion on comparison with other placental positions (47% vs 23.5%, $p < 0.05$). Immediate adverse outcomes including abruptio placentae occurred frequently in the study group (9.4%) and were *not* predictable on the basis of injury severity. When immediate adverse outcomes were excluded, there was no difference in pregnancy outcome. Four hours of cardiotocographic monitoring used as a screening tool was found to be an extremely sensitive but nonspecific indicator of immediate adverse outcomes. On the basis of these findings, it is recommended that routine screening for fetomaternal transfusion occur in all pregnant women who suffer trauma during pregnancy beyond 11 weeks' gestation and that a minimum of 4 hours of cardiotocographic monitoring occur in women >20 weeks' gestation. (Am J Obstet Gynecol 1990;162:1502-10.)

Key words: Abruptio placentae, pregnancy, injury, pregnancy outcome, fetomaternal hemorrhage

Trauma during pregnancy is associated with an increased risk of spontaneous abortion, preterm labor, abruptio placentae, fetomaternal transfusion, and stillbirth.[1-9] The frequency and time of onset of these complications are not clear and may be related to the type of injury, location of injury, gestational age, or severity of injury. This uncertainty has prompted a variety of recommendations for the management of the pregnant patient who has suffered trauma.[10-13]

This cohort study was designed to prospectively evaluate pregnant women who have suffered trauma during pregnancy, with uninjured pregnant women serving as controls. Acute complications (i.e., abruptio placentae, fetal death, rupture of membranes, onset of labor, preterm delivery), and the incidence and volume of fetomaternal transfusion, as well as pregnancy outcome, are compared.

Material and methods

From November 1985 to August 1988, 85 women presenting to William Beaumont Hospital with a complaint of trauma during pregnancy were enrolled. Subjects were included if they sustained any severity of trauma at or beyond 12 weeks' gestation. Patients with isolated distal extremity injuries were excluded. Each subject was first evaluated in the Emergency Department, and after stabilization, those patients at or beyond 20 weeks' gestation were transferred to the labor and delivery suite for a minimum of 4 hours of cardiotocographic monitoring (model 8040A; Hewlett-Packard, Palo Alto). In many cases monitoring was begun in the Emergency Department. Subjects at or beyond 20 weeks' gestation also had a complete ultrasonographic examination performed (biparietal diameter, abdominal circumference, femur length, amniotic fluid volume, placental location, cerebral ventricular diameter, and calculated estimated fetal weight). Patients <20 weeks' gestation with absent fetal heart tones, abdominal pain, or vaginal bleeding underwent a similar ultrasonographic examination. The retroplacental area was carefully evaluated in all patients for findings suggestive of abruptio placentae.

Historical information included the type of injury: motor vehicle accident, fall to horizontal, fall from height, or direct blow to the abdomen (kick, punch). If

the subject was involved in a motor vehicle accident, the restraint system used (if any), speed of the vehicle, damage to the vehicle, and patient position in the vehicle were recorded if possible. The time from injury to presentation was noted as were any symptoms or complaints on admission. A thorough physical examination and appropriate roentgenography or other diagnostic studies (e.g., peritoneal lavage) were performed as indicated.

Cardiotocographic monitoring of all study patients >20 weeks' gestation was performed for a minimum of 4 hours. The 4-hour monitoring record was evaluated for uterine contractions, baseline fetal heart rate, periodic changes, and overall assessment of fetal well-being by a single investigator who was blinded to outcome (R. P. L.). Subjects were categorized into one of five groups on the basis of the frequency of uterine contractions. Those not having contractions were identified as group 0, those with fewer than one contraction every 15 minutes were placed in group I, patients with contractions every 10 to 15 minutes were placed in group II, those with contractions every 5 to 9 minutes were put in group III, and those with contractions every 2 to 5 minutes were placed in group IV.

A control group matched for gestational age (±1 week) was selected from a large group of patients presenting to the Department of Fetal Imaging for obstetric ultrasonography. Subjects were also selected on the basis of the likelihood of obtaining complete follow-up (i.e., delivery at William Beaumont Hospital). The only exclusion criterion was a history of recent vaginal bleeding (within 1 month).

Both groups had an acid elution (Kleihauer-Betke) assay performed at the time of entry into the study. The method used has been previously described.[14] A minimum of 1000 cells were counted. The estimated volume of fetomaternal transfusion was based on the number of fetal cells seen on the smear and an estimate of maternal blood volume. Apgar score, birth weight, gestational age at delivery, and length of neonatal stay were recorded. Subjects who were delivered outside of the institution were contacted by telephone and their records reviewed for outcome.

All data were analyzed with the SAS package. Discrete variables were compared by χ^2 analysis. The two-tailed Student t test was used for continuous variables, and the Fisher exact test was used when appropriate. A p value ≤ 0.05 was considered to be statistically significant.

The study was approved by the Human Investigation Committee at William Beaumont Hospital, and appropriate consent forms were signed by each subject. Eight trauma subjects who were eligible refused admission into the study.

Table I. Demographics

	Trauma (n = 85)	*Control (n = 85)*
Age, yr (mean, range)	27.1 (17-41)	28.4 (19-39)
Gravidity (mean, range)	2.5 (1-7)	2.3 (1-6)
Parity (mean, range)	1.0 (0-6)	1.1 (0-5)
Gestational age at entry, wk (mean, range)	29.3 (12-42)	29.1 (12-41)

There was no significant difference between the two groups.

Results

A total of 170 women were enrolled in the study (85 trauma subjects and 85 controls). Outcomes were available for all pregnancies. The age, gravidity, parity, and gestational age at the time of entry are listed in Table I. Prior preterm deliveries were also noted. There was no significant difference between the two groups for any of these variables.

Injury type and severity. Motor vehicle accidents were the most frequent cause of trauma (n = 51; 60%), followed by falls (n = 22; 25.9%) and direct blow to the abdomen (n = 12; 14.1%). Falls were categorized as either fall to horizontal (n = 12) or fall from height (n = 10). Thirty-nine patients involved in motor vehicle accidents were restrained (76.5%), with one exception all subjects were in three-point restraint. Thirty-seven women were drivers of the vehicle, 12 were front-seat passengers, and two were rear-seat passengers. The severity of the motor vehicle accident ranged from minor car damage with no demonstrable maternal injury to extensive vehicle damage and critical illness of the victim at presentation (e.g., hemorrhagic shock, comatose from traumatic brain injury, multiple organ system involvement). Of all trauma victims, 75 (88.2%) had minor or no injuries on clinical examination (minor bruising, lacerations, contusions), 8 (9.4%) had moderate injuries (broken long bones, fractured ribs, extensive bruising), and 2 (2.4%) were critically ill at presentation.

Immediate adverse outcomes. Immediate adverse outcomes were prospectively defined as either abruptio placentae within 72 hours of injury, rupture of membranes within 4 hours of injury, onset of labor within 4 hours of injury that resulted in delivery during the index hospitalization, or fetal death within 7 days of the traumatic event. Table II lists all immediate adverse outcomes along with injury severity. Although both critically injured women suffered abruptio placentae, immediate adverse outcomes occurred more frequently among those less severely injured, as three of the five subjects who suffered abruptio placentae occurred in

Table II. Immediate adverse outcome

Injury severity	*n*	*Abruptio placentae*	*Ruptured membranes*	*Fetal death*	*Delivered (total)*
Minor	75	3	1*	0	5†
Moderate	8	0	1	0	1
Severe	2	2	2*	1‡	2
TOTAL	85	5 (5.9%)	4 (4.7%)	1 (1.2%)	8 (9.4%)

*Rupture of membranes occurred in addition to abruptio placentae.

†Includes two patients who were delivered without evidence of abruptio placentae.

‡Fetal death resulted from complete abruptio placentae.

Table III. Outcome of pregnancies complicated by abruptio placentae (all delivered during index hospitalization)

Patient No.	*Fetal monitor tracing*	*Apgar score*		*Venous cord pH*
		1 min	*5 min*	
1	Persistent type II decelerations	3	6	7.03
2	Tachycardia	5	8	7.16
3	Persistent type II decelerations; tachycardia	4	8	7.13
4	Deep variable decelerations; tachycardia	8	9	7.26
5	No fetal heart tones	0	0	Not performed

the minor injury group. Two of these women had entirely normal results at physical examination on admission.

Of the pregnancies that were complicated by abruptio placentae, all ended with delivery during the index hospitalization. One of the fetuses was dead on presentation as a result of a complete abruptio placentae, and the remaining four were delivered urgently by cesarean section because of abnormal fetal heart tracings. The outcomes of all pregnancies complicated by abruptio placentae are shown in Table III.

Three patients without evidence of abruptio placentae developed labor during the index hospitalization that resulted in delivery. These pregnancies were at 36, 38, and 41 weeks' gestation. No neonatal morbidity or mortality resulted from these pregnancies.

Fetomaternal transfusion. The rate of fetomaternal transfusion was 26 of 85 in the trauma group compared with 7 of 85 in the control group (30.6% vs 8.2%, $p = 0.0001$). The mean estimated volume of transfusion was 12.2 ml (range 5 to 69 ml) in the study group compared with 3.2 ml (range 2 to 8 ml) in the control group ($p = 0.02$).

In comparison with other placental locations in the trauma group anterior placental site was more frequently associated with fetomaternal transfusion (47% vs 23.5%, $p < 0.05$). There was no similar association in the control group. The physical finding of uterine tenderness also was more frequently associated with fetomaternal transfusion in comparison with absence of this finding (65% vs 32%, $p < 0.05$). No other physical finding was associated with fetomaternal transfusion. Trauma subjects who were restrained during motor vehicle accidents had a tendency to fetomaternal transfusion on comparison with those not restrained, but this difference did not reach statistical significance ($p = 0.06$). There was no definite relationship between uterine activity, fetal heart tracing abnormalities, and the risk of fetomaternal transfusion. None of the subjects demonstrated a sinusoidal fetal heart rate pattern.

The pregnancy complicated by the largest fetomaternal transfusion (69 ml) was terminated shortly after the accident because of fetal distress associated with abruptio placentae. The cord hematocrit was 36% and the neonate required transfusion after delivery. No other complications directly attributable to fetomaternal transfusion were noted. All Rho (D)–negative women who had fetomaternal transfusion were treated with Rh immune globulin in the appropriate dosage.

Pregnancy outcome. Birth weight, 1- and 5-minute Apgar scores, gestational age at delivery, type of delivery, and neonatal length of stay in both groups, excluding those subjects with immediate adverse outcomes, are shown in Table IV. When immediate adverse outcomes and their controls were excluded, there was no difference in any of the variables between the two groups.

Cardiotocographic monitoring and ultrasonography. All subjects >20 weeks' gestation were monitored for a minimum of 4 hours after the traumatic event ($n = 60$). Only four of the 60 subjects had essentially no uterine activity during the 4-hour monitoring period (6.7%). Fig. 1 illustrates the uterine activity among all contracting patients. Nearly two thirds of the subjects were having contractions at a frequency of every 2 to 5 minutes during the first hour of monitoring (group IV). The size of this group decreased progressively over the 4 hours, at which time only 28.6% of women were having contractions at that frequency. Conversely, 19.6% of women were having contractions at an interval greater than once in 15 minutes (group I) during the first hour, and this group increased in size over time to include a total of 37.5% of all subjects at the 4-hour mark. Groups II (contractions every 6 to 10 minutes) and III (contractions every 11 to 15 minutes) increased slightly over time at the expense of group IV.

All women who had immediate adverse outcomes (except one patient with only rupture of the membranes) were in group IV at some point during the 4 hours of monitoring. One woman who had a clinical apparent abruptio placentae 6 hours after the traumatic event began in group I at hours 1 and 2 and progressed to group IV at hours 3 to 6, at which time she had vaginal bleeding and eventually revealed persistent late decelerations of the fetus necessitating urgent operative delivery.

The use of tocolytic drugs was generally discouraged, but one patient was treated with parenteral ritodrine; she was seen at 28 weeks' gestation with contractions every 2 to 5 minutes after a motor vehicle accident. The frequency of uterine activity decreased over the next 45 minutes. The medication was discontinued after 90 minutes as chest pain developed. No other tocolytic therapy was begun, and contractions stopped spontaneously over the next 180 minutes. She was admitted for a total of 44 hours and was discharged without medication. She was delivered of a healthy 3.42 kg male infant at 39 weeks.

All subjects who were in groups II, III, or IV at any time during the 4-hour monitoring period were admitted beyond 4 hours (for a minimum of 24 hours). Subjects in group 0 or I during the entire 4-hour monitoring period were discharged at the end of the 4 hours unless uterine tenderness, a nonreassuring fetal monitor strip, vaginal bleeding, rupture of the membranes, or any serious maternal injury was present. Of the 60 women eligible for admission (>20 weeks' gestation), 42 were admitted beyond the 4-hour period (70%). All patients discharged at the end of the 4 hours or at 24 hours had a live birth. Gestational age at delivery, Apgar score, and birth weight were similar to those of the matched control group in all discharged patients. In patients admitted beyond the 24 hours, there was one fetal death (2.4%) and seven other deliveries (16.7%).

Ultrasonography predicted abruptio placentae in two of five patients (40%), but both of these patients had a clinically evolving abruptio placentae (vaginal bleeding and frequent uterine activity) at the time of the ultrasound. In three patients who did suffer abruptio placentae, the admitting sonogram did not suggest the diagnosis.

Comment

The management of trauma during pregnancy has evolved from a variety of protocols developed in nonpregnant trauma victims. Although these principals generally translate in very serious injuries, the less seriously injured pregnant woman is more problematic. The protocol developed herein was able to predict the major fetal morbidity experienced in this study. Interestingly, in the women who did not suffer immediate adverse outcomes, the accident appears to have had a minimal, if any, impact on pregnancy outcome in terms of birth weight, gestational age at delivery, or Apgar score. This finding is important to allay the fears of both the obstetrician and the pregnant woman after she is discharged home following the monitoring period. Nonetheless, it is important to instruct the patient to return if any signs or symptoms of preterm labor or abruptio placentae do occur after discharge, as the apparently rare episode of delayed abruptio placentae has been described.[15]

Several studies have noted that the incidence of abruptio placentae after major automobile accidents varied between 6% and 35%, but most of these series involve women who have suffered major injuries.[2, 3, 12] In this series, which involved mostly minor trauma, the incidence of abruptio placentae was 5.9% (4.0% in the minor injury group). Importantly, it appears that even relatively minor deformation forces are sufficient to shear the placental attachments away from the decidua basalis. It is clear that neither physical findings nor the severity of injury is able to rule out immediate adverse outcomes. Routine cardiotocographic monitoring for a minimum of 4 hours appears to be very sensitive for predicting immediate adverse outcomes including abruptio placentae. Ultrasonography does not appear to be particularly useful in predicting abruptio placentae after trauma (sensitivity = 40%). Nonetheless, ultrasonography may still be useful in these patients for other reasons (estimating fetal weight and gestational age, biophysical profile, amniotic fluid volume).

The current protocol recommended that tocolysis not be attempted, although the ultimate decision was left to the attending physician. Of the 35 women who were having frequent contractions during the monitoring period (group IV, 2 to 5 minutes apart), five subsequently suffered an abruptio placentae requiring delivery, and three others were delivered of their infants during the index hospitalization (at 36, 38, and 41 weeks). Tocolysis was discouraged as it was felt that regular uterine activity after trauma was a result of abruptio placentae until proved otherwise. This hypothesis was mostly borne out during the study because five of the eight patients who were delivered did suffer an abruptio placentae. In those women with frequent contractions, contractions stopped in 90% without tocolysis. Of those patients who were delivered during the index hospitalization without evidence of abruptio placentae, all were at or near term, and no serious fetal morbidity resulted from these deliveries. Uterine activity after trauma may result from a uterine "contusion" resulting in extravasation of blood from myometrial capillaries and subsequent irritability. As this extravasated blood is resorbed, the uterine irritability diminishes. We feel that the initial presentation of

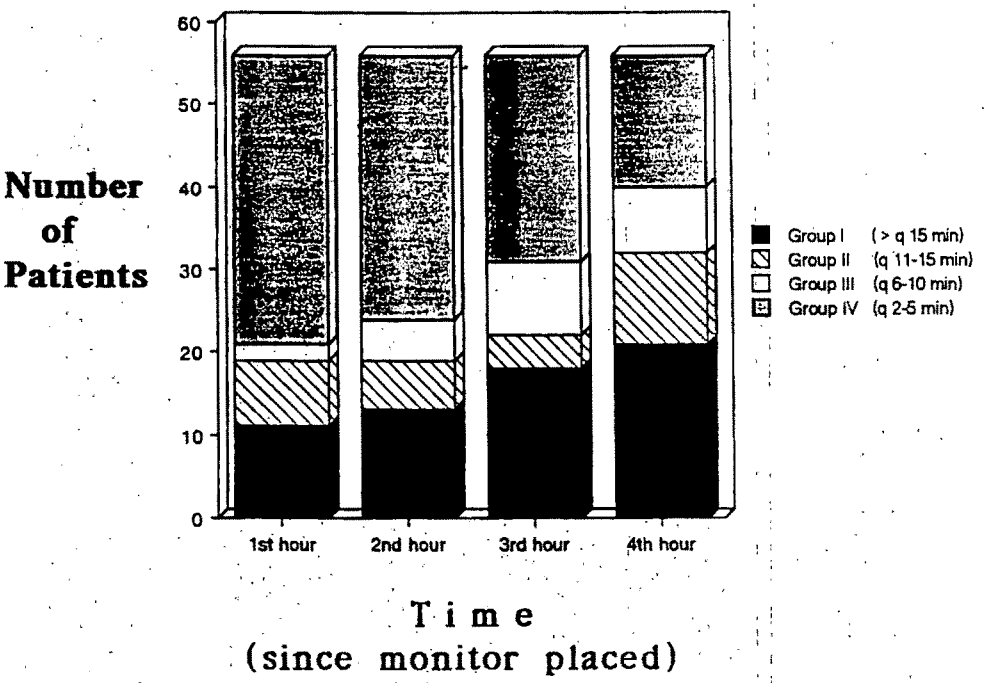

Fig. 1. Number of patients with uterine contractions at various frequencies during the first 4 hours of monitoring ($N = 56$).

Table IV. Pregnancy outcome (excluding immediate adverse outcomes)

	Trauma	*Study*
Birth weight (kg, mean ± SD)	3.44 ± 0.58	3.53 ± 0.57
Gestational age at delivery (wk, mean ± SD)	38.9 ± 4.5	39.8 ± 2.2
Apgar score		
1 min	7.5	7.7
5 min	8.8	8.9
Delivery type (% cesarean section)	21	24
Neonatal length of stay (days ± SD)	4.1 ± 4.0	4.1 ± 6.8

There was no significant difference for any variable between the two groups.

abruptio placentae and "contusion" are indistinguishable and tocolysis should not be attempted.

Pregnant patients who suffer trauma are clearly at risk for fetomaternal transfusion; this finding confirms an earlier report by Rose et al.[5] Neither the severity of injury nor the presence of uterine activity was predictive of fetomaternal transfusion, although an anteriorly positioned placenta and the presence of uterine tenderness did place patients at increased risk. With one exception, patients with fetomaternal transfusion experienced no difference in pregnancy outcome on comparison with controls. This contrasts with results of Rose et al.,[5] where three of nine fetuses who suffered fetomaternal transfusion had some demonstrable abnormality. Fetuses who suffer fetomaternal transfusion appear to be at some risk for adverse outcome, although most will not experience problems. This group of patients is at risk for Rh sensitization in Rh-negative mothers and should be treated with adequate prophylaxis. The risk for fetomaternal transfusion is high (30.6%) after trauma during pregnancy, and if testing is not readily available to assess fetomaternal transfusion, routine administration of Rh immune globulin is recommended in addition to continuous fetal monitoring.

In conclusion, this study suggests that all patients >20 weeks' gestation who suffer trauma during pregnancy should be monitored for a minimum of 4 hours as the risk for abruptio placentae is significant and associated with frequent uterine activity. In addition, all patients >12 weeks' gestation should have Kleihauer-Betke analysis to detect fetomaternal transfusion with Rh immune globulin administration to appropriate candidates. Although only one fetus appeared to suffer any serious morbidity on the basis of fetomaternal transfusion in our series, serial testing may be indicated to substantiate that further bleeding does not occur after the initial test. If serial testing is indicated, it is not clear whether testing should occur in all patients or only those with fetomaternal transfusion present initially.

We express our appreciation to Drs. Christine Comstock, Robert Bree, and S. S. Yang for their significant contributions to this study.

Discussion

DR. WARREN M. CROSBY, Oklahoma City, Oklahoma. This is important work. The design of the study is superb and so we can rely on the lessons learned. The authors confined their study to the group of pregnant trauma victims in which we should have the most interest: those mothers that do not have life-threatening injuries. Here the obstetrician and emergency physician can learn which maternal findings and treatments correlate best with fetal outcome. Such a study is sorely needed to provide scientific evidence on which to rely when one is advising not only the pregnant trauma victims themselves as to the likely outcome of their pregnancy but their lawyers as well, who seem bent on establishing trauma as the certain cause of a bad perinatal outcome, no matter how unlikely that conclusion seems to be.

I wish to emphasize two areas of importance:

1. I am delighted to see that 76.5% of the motor vehicle accident victims were wearing restraints. This is a much higher percentage of women drivers wearing seat belts than national surveys have found. There is little doubt that the three-point restraint, available in all automobiles today, is very effective at reducing injury. This is particularly true of the pregnant driver because belts are very successful in preventing impaction of the mother's pregnant abdomen and chest into the steering wheel. Indeed, the overrepresentation of belted victims in this study attests to this fact. Nonbelted victims that are injured at all are likely to have more serious internal injuries, injuries severe enough to prevent their having been included in this study.

2. The most important finding is that if the trauma did not produce an adverse outcome within the first day or two after the traumatic event, the trauma did not affect the pregnancy at all.

This carefully documented observation brings up the question of the so-called "delayed abruptio" following trauma. To my knowledge there have been only two cases of "delayed abruptio" reported. Both were unbelted drivers in the early third trimester.[1,2] Both hit the steering wheel and had noncatastrophic injuries. In one case the nonstress was nonreactive on admission, but clear-cut fetal compromise was not seen until the membranes ruptured 5 days later. The fetus was thought to be uncompromised in the second case for 5 days, when bleeding and contractions began. The patient was transferred to a tertiary care center and continuous fetal monitoring was not remarkable until the next day when vaginal bleeding and uterine tenderness developed along with increased uterine contractions. Late decelerations were seen and a cesarean delivery was done. Both of these fetuses were small for dates, and both lived. In both cases extensive placental separation was found.

When trauma results in disruption of the placental attachments to the decidua, the bleeding that occurs at that time is usually self-limited. When the bleeding is not self-limited, the typical signs of severe placental separation occur, beginning within the first few hours after the traumatic event. When the amount of separation is less, the blood is released into the decidua clots promptly. The decidual cells involved in the process release prostaglandins, which cause almost all trauma victims in late pregnancy to have uterine contractions. Only 7% of the victims in this study did not have uterine contractions within the first few hours after admission. Again, the process usually is self-limited. Uterine contractions stop within a few hours as they did in 91% of the victims reported here. Labor may indeed progress in some, probably related to the amount of decidual damage, the release of decidual prostaglandins, and the length of the pregnancy. In those pregnant trauma victims that are not delivered within the first 48 hours or so, the clot organization process is underway. The area of separation ultimately becomes an infarct. The process bcomes stable in virtually all cases within 24 to 48 hours of the initial event. In my opinion, the two cases of "delayed abruptio" were not "delayed" at all. It was the diagnosis that was delayed. The fetus was just so compromised that it didn't quite die initially, and diagnosis was not made until increased uterine activity or better observation a few days later called attention

to its plight. In both cases delivery occurred within 6 days of the traumatic event, and in both cases the fetus lived.

I am aware of two prospective studies of pregnant trauma victims so far unpublished, in addition to the one presented today and the one my colleagues and I reported in 1970.[3] These four prospective studies account for 797 pregnant victims of trauma. There were 17 cases of abruptio placentae among the 797 cases, and each was identified within the first few hours after the traumatic event. In short, I don't believe that there is such a thing as "delayed abruptio." The placental separation occurs at the time of the trauma and either is severe enough to cause labor, fetal death, maternal bleeding, and the like or is self-limited, with the initial symptoms of uterine contractions or spotting stopping within 48 hours in virtually every case.

Thus I agree with the authors, as well as Higgins and Garite,[2] that the fetal monitor should be applied as soon as appropriate after immediate emergency measures are taken when the pregnant trauma victim arrives at the hospital. If the fetus is far enough along to be considered viable, fetal monitoring should probably be continued for a period of a few hours to begin with. If the patient is totally asymptomatic and no evidence of injury or fetal distress can be found, it is a rare patient indeed that would return later with a dead fetus or bleeding. For patients with symptoms or signs that indicate the possibility of more severe injury, more prolonged observation in the hospital will be appropriate. I suggest that such patients have fetal monitoring during the time that they are in the hospital, because, during observation of the mother for serious injury, the fetus may very well be ignored by physicians and nurses that don't normally care for pregnant women.

But when do you stop the monitoring? When is it safe to let the patient go home? I think the best advice is to use the information presented today and tell the patient that "there are a few cases in which things turned bad several days after a traumatic event, but this is rare. It occurs much less frequently than one in a thousand cases." And then add: "But, Mrs. Smith, if you insist upon it, we'll keep you on the monitor for a full week. Since no case of trauma-related abruptio has ever been reported longer than a week later, you can go home with confidence then. This doesn't guarantee you a healthy baby. It only removes the possibility of the fetus dying from a placental separation that we haven't been able to discover." This strategy ought to allow you to let most people go home in a reasonable time. It also transfers the responsibility for going home at that time from you to the patient.

Dr. David B. Cotton, Houston, Texas. Dr. Pearlman and his colleagues have studied 85 women suffering varying degrees of trauma during pregnancy and compared them prospectively with a control group matched for gestational age. In this study, which represents the experience of a large, sophisticated community hospital, motor vehicle accidents were the most frequent cause of trauma. Overall 97.6% of trauma cases were classified as mild to moderate and only 2.4% as critical. However, three of the five cases of abruptio placentae seen in the study, as well as two cases of preterm delivery, occurred in the minor trauma group. These five cases combine to give a 6.7% incidence of immediate adverse outcome in minor trauma cases, which are defined as minor bruising, lacerations, or contusions. This information emphasizes strongly that even minor trauma during pregnancy must be taken seriously by the obstetrician and a consistent and thorough evaluation implemented.

The incidence of fetomaternal transfusion in the trauma group was 30.6% as compared with 8.2% in the control group. The mean volume of fetomaternal transfusion in the trauma group (12.2 ml) was three times that of the control group (3.2 ml). Additionally, an anterior placental location site appeared to be much more susceptible to trauma as fetomaternal transfusion was twice as frequent in anterior placentas than other placental locations.

Importantly, for those evaluating pregnant trauma victims, uterine tenderness was associated with a fetomaternal transfusion 65% of the time. However, 32% or roughly one third of patients with a demonstrable fetomaternal transfusion had no significant uterine tenderness.

Additionally, in this group undergoing fetal monitoring for a minimum of 4 hours there was no relationship between uterine activity or fetal heart rate tracing abnormalities and the risk of fetomaternal transfusion. It would appear from these data that there are no clinically reliable signs or symptoms that predict fetomaternal transfusion in trauma cases. In cases of even minor trauma involving Rh-negative patients a Kleihauer-Betke test must be considered mandatory.

Ninety-three percent of patients in this study had some uterine activity following trauma. In this protocol all patients with uterine contractions more frequent than one every 10 minutes were admitted for a 24-hour observation period. All patients experiencing immediate adverse outcomes had contractions every 2 to 5 minutes (group IV) at some time during the initial 4-hour monitoring period. The data from this study suggest that a simple 4-hour fetal monitoring period combined with a Kleihauer-Betke screen will identify virtually all the fetal morbidity associated with trauma in pregnancy.

Last, and for the patient perhaps most important, this study documents that when pregnant patients undergo trauma but do not have an immediate adverse

outcome there are no subsequent effects on maternal, fetal, or neonatal outcome.

Questions that this study raise include the following:

1. Is William Beaumont Hospital a level I referral center for trauma? If not, perhaps this explains the relatively low incidence of critical trauma.

2. Was there a gestational age below which immediate adverse outcomes such as abruptio placentae or preterm delivery did not occur in the minor trauma group? Perhaps minor trauma before 20 weeks' gestation rarely results in immediate adverse outcome.

3. In those patients with minor trauma and abruptio placentae or preterm labor did each patient experience a blow specifically to the abdomen?

4. Is the 8.2% incidence of fetomaternal transfusion in the control group somewhat higher than one would normally expect?

5. What was the incidence of fetomaternal transfusion in the minor versus moderate trauma group and were these mostly concentrated in the late third trimester?

6. Last, although this study has defined the incidence and degree of fetomaternal transfusion with trauma during pregnancy, what is the purpose of documenting fetomaternal transfusion in patients who are Rh-positive if management primarily hinges on fetal heart rate monitoring?

The authors are to be congratulated for a well-designed, clinically relevant study.

Dr. Charles A. Stedman, New Orleans, Louisiana. There have been several studies of ≥1000 consecutive Rh-negative patients who after the ultimate trauma, the delivery process, have been found to have significant fetal-maternal hemorrhage. Only three to ten patients per thousand have been noted under those circumstances. How do the authors explain the fetal-maternal hemorrhage incidence of 80 per thousand in their control group? This suggests some sort of method error in the laboratory.

The second question is do they get their Kleihauer-Betke results back within 4 hours? At most institutions a pathologist is required to give those results. In most of the hospitals in which I've worked, the pathologist is unavailable at nighttime, and we have to wait until the next morning for results.

Dr. Sharon L. Dooley, Chicago, Illinois. I think this is a wonderful study that tremendously advances our knowledge. I have a comment about terminology. Dr. Pearlman used the term *severe fetal acidosis* to show the cord artery pH values for the fetuses that required urgent delivery. For a long time, and for reasons that are not clear, we used a pH of 7.20 as the lower limit of normal for cord artery pH. There are now considerable data published that indicate that the lower limit of normal is closer to 7.10 or 7.12 and that a pH really has to be less than 7.00 before we call that a severe fetal acidemia.

I think it's time for us all to stop "digging our own graves" for the lawyers and use proper terminology.

Dr. James R. Scott, Salt Lake City, Utah. I wonder if you could give us details about the management of the cases of abruptio placentae and specifically what happened with the one stillborn infant. The reason I ask is that many of these fetuses are premature when being monitored, and we consider it to be ominous if there are any abnormalities. I can recall at least one patient who was being monitored and the fetal heart rate suddenly dropped to zero.

Dr. Daniel A. Rightmire, Springfield, Illinois. Do the authors have information about biochemical assays, such as maternal serum α-fetoprotein or β-human chorionic gonadotropin, which might be markers of trophoblast injury or death available in a hospital that does not have reliable Kleihauer-Betke techniques?

Dr. Pearlman (Closing). Dr. Cotton, Beaumont Hospital's emergency center is a level I trauma referral center and sees approximately 75,000 patients per year. However, because of its suburban location, we do not see the same frequency of severe trauma as an inner city institution.

The earliest gestational age at which we saw an immediate adverse outcome was 26 weeks—an abruptio placentae. However, I would not discount the possibility of abruptio placentae before that gestational age as it most definitely occurs. Prior studies have also shown that the more advanced a pregnancy is, the more susceptible the fetus and placenta are to injury.[1]

The issue of whether patients experienced a direct blow to the abdomen is particularly problematic. When patients who have been involved in motor vehicle accidents are asked if they've been struck directly in the abdomen, the answer is not always reliable. Many patients that we saw who stated they were not struck in the abdomen had seat belt bruises or other evidence of injury to the abdomen, so I don't think you can rely on history alone. In terms of immediate adverse outcome, all our patients, either historically or by examination, had evidence of a direct blow to the abdomen.

The incidence of fetomaternal transfusion in our control group was approximately 8%, which is similar to the 6% reported by Rose et al.[2] in their prospective trauma study's control group. In addition, there are two additional studies that evaluated the incidence of fetomaternal transfusion in normal pregnancies, revealing some evidence of fetomaternal transfusion in at least 5% to 10% during the third trimester, although they did count 5×10^4 maternal cells.[3, 4] I think that our results are similar to these studies.

With regard to the relationship between fetomaternal transfusion and gestational age, most of these injuries occurred during the third trimester, so a majority of transfusions were found in this group. However, we saw evidence of fetomaternal bleeding in a pregnancy of 15 weeks. So I think that the 12-week limit for testing is reasonable (i.e., when the uterus becomes an abdominal organ and is susceptible to injury).

As Dr. Cotton stated, the major purpose of documenting fetomaternal transfusion is to decrease the incidence of Rh isoimmunization in the Rh-negative patient. However, one of the fetuses in this study suffered a 69 ml transfusion and on continued monitoring had an aminous fetal heart tracing. The fetus was delivered

and was severely anemic at birth, requiring blood transfusion. That was our only complication related directly to fetomaternal transfusion. The only other study that prospectively evaluated fetomaternal transfusion after trauma exhibited even a higher frequency of complications related to the fetomaternal transfusion.[2] So I think that Kleihauer-Betke testing in all patients, whether Rh negative or Rh positive, is justified.

Regarding the question about the use of the term *fetal acidosis,* I agree that the nomenclature is evolving with regard to defining fetal acisosis; however, I think it is clear that three of the four venous pH values are lower than what we generally consider to be normal.

Dr. Scott asked about the history of the stillborn infant. That case report actually is already published.[5] Briefly, this was a woman at 32 weeks' gestation whose car was struck by a cement truck, and she was trapped inside the car for approximately 45 minutes. Her fetus was dead on presentation to the emergency center. The patient also had multiple severe intraabdominal injuries and underwent laparotomy. Cesarean section was done at the time of laparotomy because she also had an unstable pelvic fracture. The placenta was anterior and completely separated from the uterine wall, which explains the fetal loss. There was no evidence of direct fetal injury on examination of x-ray film.

We do not have any information on β-human chorionic gonadotropin or maternal serum α-fetoprotein in these patients. I would like to mention two things regarding maternal serum α-fetoprotein for assessing the need for isoimmunization prophylaxis. First, you cannot accurately determine the volume of the transfusion that prohibits the reliable administration of Rh immune globulin. Second, you would need a preinjury maternal serum α-fetoprotein level to determine the presence of fetomaternal bleeding, and this may or may not be available.

Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—Preliminary data

Jyothi Raman, MS,[a] Dipali V. Apte, BS,[a] M. Joan Dawson, PhD,[a] Stanley J. Bobowski, MD,[c] and Suzanne R. Trupin, MD[b]

Urbana-Champaign, Illinois

Biochemical study of tissue biopsy samples by magnetic resonance spectroscopy involves relatively small capital and running costs and could become a routine diagnostic or screening procedure if its utility were to be adequately demonstrated. We have demonstrated feasibility of evaluation of endometrial biopsy samples by magnetic resonance previous to histopathologic examination. Preliminary comparisons of magnetic resonance spectra with histopathologic evaluation indicates that in at least some instances, magnetic resonance may be the more sensitive indicator of disease. (AM J OBSTET GYNECOL 1990;162:1511-7.)

Key words: Magnetic resonance spectroscopy, magnetic resonance imaging, 31-P nuclear magnetic resonance, endometrial carcinoma, histology, biospy samples

The first clinical investigation with magnetic resonance was undertaken by an obstetrician and gynecologist. In their pioneering work, Odeblad and Bryhn[1] used magnetic resonance to study properties of mucous secretions from the cervical glands and predicted that magnetic resonance would be useful in clinical diagnosis. Their predictions have been realized by the presence of magnetic resonance imaging (MRI) facilities associated with hospitals and medical centers throughout the world. Whereas MRI has become a familiar tool to physicians, magnetic resonance spectroscopy (MRS), which allows the noninvasive investigation of the metabolism of cells and tissues, is less well known. The potential of MRS in detecting and monitoring biochemical alterations in diseased tissues was first shown in studies of Duchenne muscular dystrophy and a variety of metabolic myopathies.[2,3] These and subsequent studies have raised the hope that diseases might be detected by noninvasive monitoring of cellular biochemistry.

The past decade has seen enormous advances in MRI and MRS techniques, and it is now possible in some centers to obtain spatially resolved metabolic information in normal individuals and patients. However, although virtually all of the effort to develop clinical applications of MRS is focused on localized spectroscopy in conjunction with MRI, such examinations are expensive and thus limited to cases of clear need. We are exploring the alternative possibility that MRS of biopsy samples, with its relatively low capital and running costs, could become an effective supplement to histologic evaluation, or be used as a mass screening method for early detection of some gynecologic diseases.

Our interest in this possibility grew as a result of findings in our own and other laboratories[4-7] that MRS of female reproductive tissues shows specific characteristics that change with physiologic status and with common pregnancy disorders and gynecologic diseases. We have therefore designed and built a double tuned phosphorus 31 and proton probe for rapid and nondestructive MRS of endometrial biopsy samples that are subsequently evaluated histologically. Preliminary comparisons of nuclear magnetic resonance spectra of myometrium and endometrium with histopathologic evaluation indicates that in at least some instances, MRS may be the more sensitive indicator of the presence of disease.

Material and methods

Endometrium was aspirated from two normal volunteers during the proliferative and secretory phases of the menstrual cycle. Endometrial samples were obtained from eight patients by aspiration or by curettage of the hysterectomy specimens, and a total of 11 diseased myometria have been examined. Sections of hysterectomy samples (both endometrium and myometrium) were taken such that diseased tissued, grossly normal tissue at the site of disease, as well as tissue far removed from the diseased area were obtained. Fig. 1. ^{31}P magnetic resonance spectrum of proliferative endometrium obtained by aspiration from a normal volunteer. The tissue was bathed in oxygenated De Jalon's solution at 4° C within a home-built small-sample MRS probe and the spectrum obtained over a 4-hour period as described in Methods. *PME,* Phosphomonoester; *Pi,* inorganic phosphate; *PDE,* phosphodiester; *PCr,* phosphocreatine; *NP,* nucleoside phosphates; *NAD + NADP,* pyridine nucleotides; *UDPG,* uridine disphosphoglucose.

formed written consent was obtained in all cases and the study was approved by the Institutional Review Board of the University of Illinois.

All samples were immediately placed in physiologic salt solution (De Jalon's solution) that was precooled and prebubbled with a mixture of 95% oxygen and 5% carbon dioxide gases. The samples were immediately transported on ice in a thermally insulated box to the spectrometer.

^{31}P nuclear magnetic resonance spectra were obtained with a vertical high-resolution wide-bore spectrometer (GN300, General Electric, Freemont, Calif.) operating at 121.5 MHz. Spectra from hysterectomy samples (2 to 5 gm) were acquired with a 20 mm conventional probe with 20 μsec pulse duration at 1.5 second intervals, averaged over 50 minutes. Biopsy samples (50 to 100 mg) were studied (15 μsec pulse duration at 500 ms intervals, averaged for approximately 4 hours) in a home-built small-sample probe[8] that contains a flattened solenoidal radio frequency coil immersed in Fluorinert (purchased from 3M, Minneapolis, Minn.) and mounted horizontally. The acquired signals were exponentially multiplied by 30 Hz, but no other signal enhancement procedures were applied. Resonance frequencies of the phosphorus signals were measured in relation to that of an internal standard (phosphocreatine, or in its absence, the α-nucleotide phosphate peak) in parts per million. Positions of the internal standard were verified by use of an external standard of 0.1 mol/L hexachlorocyclotriphosphazene (purchased from Aldrich, Milwaukee, Wis.). Data analysis was performed as described previously[7] except that absolute calibration of peak intensities was not attempted. Tissues were placed in formalin and returned to the pathologist after the MRS study was concluded. The time from obtaining the specimen to placing it in formalin was approximately 5 hours for the biopsy specimen and 1 hour for the hysterectomy samples.

Results

Fig. 1 shows a ^{31}P spectrum of proliferative endometrium obtained by aspiration from a normal volunteer, and maintained in oxygenated physiologic salt solution. The peaks show the presence of nucleoside phosphates, primarily adenosine triphosphate, uridine diphosphoglucose, inorganic phosphate, and multiple peaks in the phosphomonoester and diester regions of the spectrum. These assignments are based on previous ^{31}P studies of similar tissues. The phosphomonoester region contains contributions from phosphoryl derivatives of choline and ethanolamine, which are precursors of membrane phospholipids, and perhaps also from sugar phosphate intermediates of metabolism. The phosphodiester region of the spectrum of living tissues typically contains resonances from glycerol-phosphoryl choline and glycerol-phosphoryl ethanol-

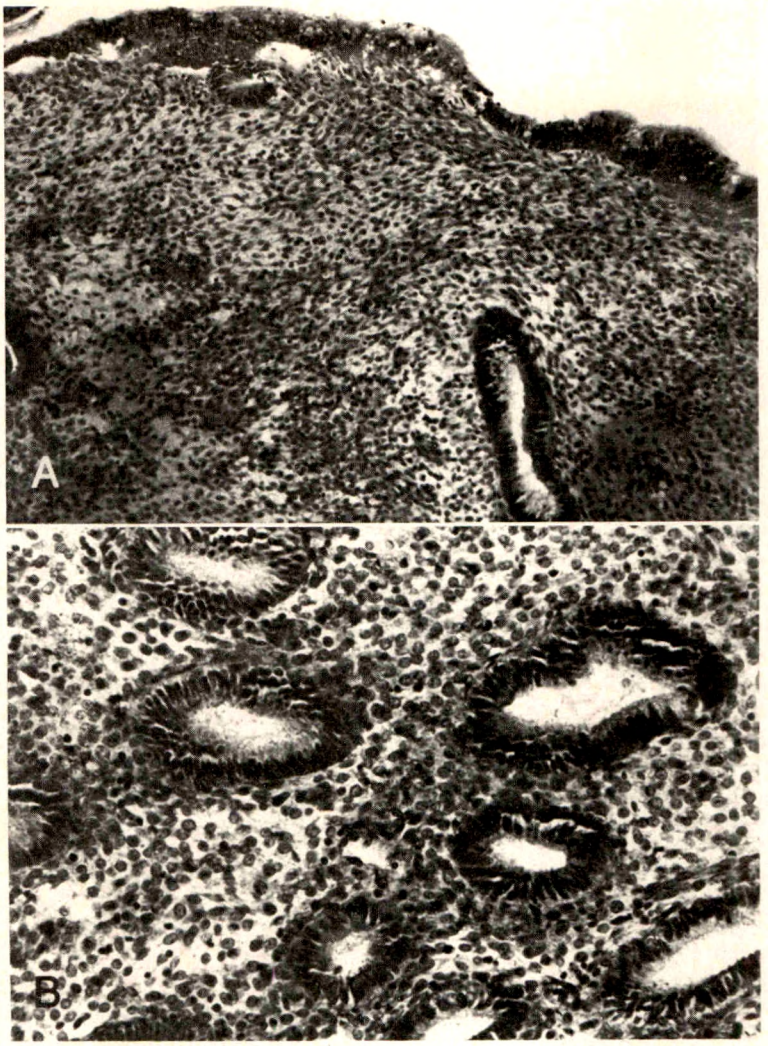

Fig. 2. Hemotoxin and eosin-y stain of the normal proliferative endometrium from which the spectrum shown in Fig. 1 was obtained. The specimen was preserved in formalin after MRS examination in a 7 Tesla magnetic field. **A,** Endometrial epithelium. (Original magnification ×160.) **B,** Integrity of the endometrial glands. (Original magnification ×640.)

amine, which are membrane phospholipid degradation products. Resolution of the phosphomonoester and diester regions of the spectrum of endometrial samples into their individual components requires MRS studies of extracts prepared from this tissue, or, alternatively, studies of the living tissue in the presence of a higher magnetic field.

Fig. 2 shows the histologic sections prepared by the pathologist from the tissue that yielded the spectrum shown in Fig. 1. The pathologist reported no deterioration and thus no difficulty in evaluating the presented tissue; as shown in Fig. 2, both glands and epithelial membranes are well preserved. Samples that have been investigated by MRS and subsequently evaluated by histology include proliferative (n = 3) and secretory (n = 1) endometrium obtained from normal volunteers as well as endometrial and myometrial samples obtained from patients who had hysterectomies because of multiple leiomyomas (n = 8), adenomyosis (n = 2), and endometrial hyperplasia (n = 1). In all 15 cases the tissue samples appeared to be unaffected by the MRS evaluation.

Comparison of spectral and histologic characteristics of biopsy and hysterectomy samples is now underway. We have obtained specimens of grossly abnormal tissue (representing the diseases previously listed), tissue that appears to be normal by gross inspection but is as near as feasible to the site of the lesion, and tissue located a few centimeters distant from the lesion. We also obtained samples of endometrium in cases of myometrial lesions and vice versa. Our preliminary studies on the 11 cases investigated by both MRS and histologic analysis indicate that histologically normal tissue obtained a few centimeters distant from a lesion of the same

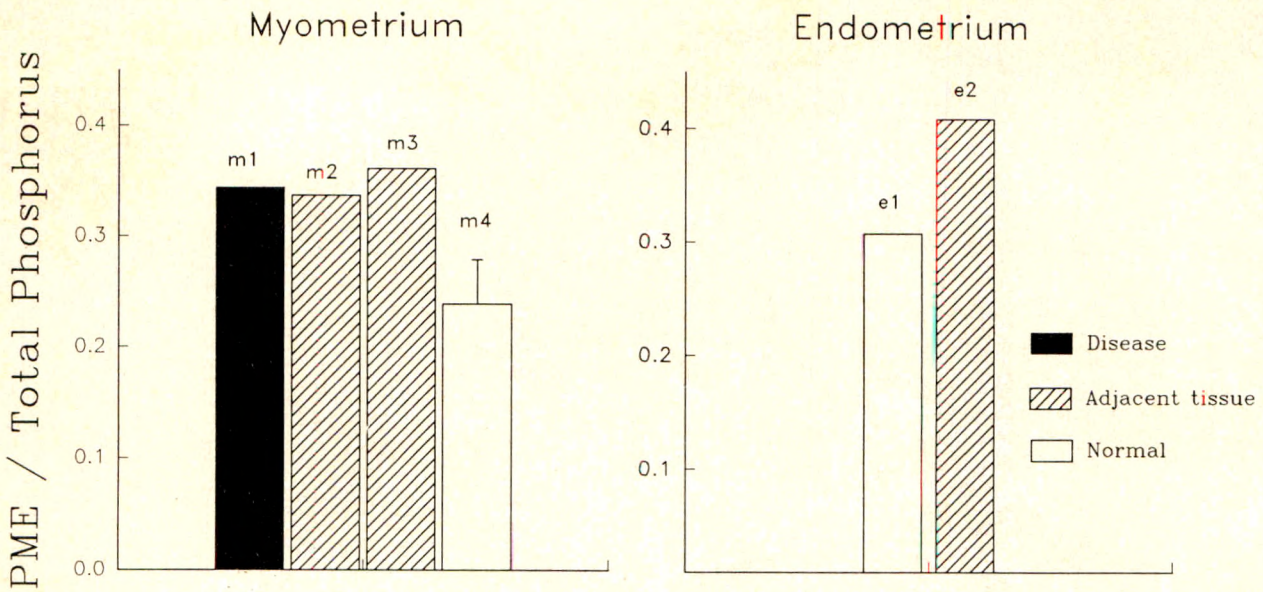

Fig. 3. The effect of leiomyoma on phosphomonoester levels of adjacent tissue in the human myometrium and endometrium. Histogram of the signal intensity in the phosphomonoester region divided by the total measurable intensity in the ^{31}P spectrum. Myometrial and endometrial tissues were obtained from the uterus of a 38-year-old patient who had a hysterectomy for multiple leiomyomas. Myometrium: *m1*, a single specimen of a subserosal leiomyoma; *m2*, myometrial tissue sectioned immediately adjacent to the site of the leiomyoma. Histologic study revealed the presence of both normal and abnormal tissue; *m3*, myometrial tissue section more than 5 cm away from the site of the lesion. Histologic study revealed only normal myometrium. *m4*, Mean and standard error of results on 12 normal myometrial specimens from our earlier study.[7] Endometrium: *e1*, average of two control values obtained from tissue aspirated from healthy volunteers at the same stage of the cycle; *e2*, endometrial curettage close to the diseased area of the myometrium.

tissue type shows abnormally high intensity in the phosphomonoester region of the spectrum. For example, histologically normal tissue obtained within 5 cm of a leiomyoma has a 1.2-fold increase in phosphomonoester, compared with controls (8 cases, 12 controls, $p < 0.03$). In addition, the leiomyomas appear to be associated with abnormalities in spectra from adjacent endometrium and endometrial lesions are associated with abnormalities in spectra of adjacent myometrium. These spectral abnormalities are particularly apparent in the phosphomonoester region.

Our preliminary findings are exemplified by the data shown in Fig. 3, obtained from a patient with multiple leiomyomas. As shown by the bar graph, the leiomyoma shows high phosphomonoester peak intensity compared with control values obtained in a previous study.[7] The high phosphomonoester of the leiomyoma is also observed in histologically normal tissue as far as approximately 5 cm distant from the lesion. In addition, there is a relative increase in the intensity of the phosphomonoester peak in the spectrum from the endometrial tissue curettage from near the site of the leiomyoma compared with endometrial tissue obtained by aspiration from two normal volunteers.

Comment

In this preliminary study we have obtained meaningful ^{31}P magnetic resonance spectra from endometrial biopsy samples, and can therefore conclude that biochemical evaluation of endometrial biopsy samples by MRS is feasible. We have also found that there is no deterioration of the specimen as a result of the MRS analysis of the biopsy. Thus the first prerequisites for use of MRS in conjunction with histology of biopsy samples is satisfied, leading to possible applications in gynecology and other clinical fields.

MRS studies of tissue biopsy samples involve relatively small capital and running costs and could therefore become routine diagnostic or screening procedures if their use were to be adequately demonstrated. Our preliminary studies are promising in that comparison of MRS with histopathologic evaluation indicates that in at least some instances MRS may be the more sensitive indicator of the presence of disease. This is exemplified by apparent changes in the phosphomonoester region of the spectrum in histologically normal tissue near the sites of endometrial or myometrial lesions. Metabolites that give rise to signals in the phosphomonoester region of the ^{31}P spectrum are cyto-

plasmic constituents, and have never been found in extracellular fluids or bathing medium; thus diffusion from the site of formation appears to be an unlikely explanation for our results. Our results are consistent with a number of reports that phosphomonoester intensity is elevated in diseased tissue, including benign and malignant neoplasm. Particularly relevant is the finding that phosphomonoester peak intensities are elevated in breast cancers, and are higher in malignant than benign breast tumors.[9]

Further study will be required to fully characterize the biochemical changes that occur in histologically normal tissue that is in proximity to uterine lesions. In addition, these preliminary results suggest that further development of small-sample spectroscopic techniques is worthwhile. We are currently improving our probe design and evaluating novel methods of extracting NMR signals from noisy spectra. Finally, application of additional magnetic resonance techniques, including analysis of other magnetically sensitive nuclei, may prove equally fruitful to the ^{31}P studies described here.

We thank Dr. Y. T. Ho and Ms. Della Moon, Department of Pathology, Burnham Hospital, Champaign, Illinois; and Dr. S. Nandkumar, Assistant Professor of Pathology, College of Medicine, University of Illinois, Urbana-Champaign, for their help and advice. We acknowledge the cooperation and help of the graduate students in the laboratory, especially Brian B. Roman, and members of the staff at Womens' Health Practice, Champaign, Illinois.

Discussion

Dr. J. G. Quirk, Little Rock, Arkansas. Significantly, the first clinical investigation that used MRS studied proton magnetic resonance of human cervical mucus during the menstrual cycle. That pioneering study by Drs. Odeblad and Bryhn was published in 1957.[1] Over the past 6 years investigators led by Dr. Joan Dawson at Urbana-Champaign have accelerated the application of MRS to studies of both the normal and diseased female reproductive tract.

The development of MRS in biology is based on the fact that certain atomic nuclei found in relative abundance in biologic material—^{1}H, ^{13}C, ^{31}P—will absorb radiation at characteristic frequencies when they are oriented by a strong magnetic field. Importantly, nuclei of the same element, when found in different chemical environments, absorb energy at different frequencies. This displacement of the resonance frequency from some chosen reference frequency produces distinct, so-called chemically shifted spectral lines. As a result it is possible to observe specific atoms, for example, phosphorus in the α-phosphate group of adenosine triphosphate, even in complex solutions or in the solid state.

This article represents preliminary data in the authors' continuing attempt to correlate disease state in the female reproductive tract with alterations in ^{31}P MRS. Data are presented that suggest that phosphomonoester is elevated in all tissues (myometrium, myoma, endometrium) obtained from a uterus removed for uterine leiomyomas. This preliminary result parallels their previous findings in myometrial tissue obtained from uteri containing adenocarcinoma[2] and is supported by other studies of cultured colonic adenocarcinoma cells and metastatic adenocarcinoma of the liver.[3,4] In addition, the authors have demonstrated previously that, compared with the normal nongravid uterus, tissue obtained from the gravid uterus at term contains an excess of phosphodiesters, phosphocreatine, and uridine diphosphoglucose.

In aggregate, the authors have thus far described the ^{31}P magnetic resonance spectra of myometrium and endometrium in the pregnant and the nonpregnant state, in the presence and absence of endometrial adenocarcinoma, and in the presence and absence of uterine leiomyomas. They have demonstrated consistent but variable changes in spectra effected by the endocrine milieu and pathologic status of these tissues. Of particular interest to me are the changes in precursors

and products of membrane glycerophospholipids described in their work. I must admit that I cannot at this time interpret these results, but it would be reasonable to assume that these findings reflect alterations in the activity of the enzymes that regulate membrane metabolism and signal transduction across the plasma membrane.

Pregnant women and women with adenocarcinoma of the endometrium are known to express several of the protooncogenes.[5,6] The products of some of these genes varicusly alter signal transduction across the plasma membrane, have protein kinase activity, or regulate adenylate cylase, all processes intimately involved with phosphate metabolism. It would be exciting to learn if changes in ^{31}P MRS associated with these conditions could be correlated in a meaningful way with the expression of protooncogenes known to affect the metabolism of phosphorus-containing compounds within these cells.

I have several questions for the authors about the article. (1) In the Material and methods section, you state that absolute calibration of peak intensities was not attempted. If this is true, can we be certain that the fraction of the total phosphorus signal that is contained in the phosphomonoesters is truly elevated? (2) Because you suggest that MRS analysis of biopsy samples is less expensive than in vivo magnetic resonance spectroscopy, could you give us an idea of the present capital investment and running costs for this equipment? (3) Have you been able to extend your findings to myometrial specimens obtained for other pathologic states? (4) What are the prospects for resolving individual clinical moieties contained in the phosphomonoester and phosphodiester peaks?

Only 20 years ago, clinically useful imaging science was limited to reading x-ray films and looking down the barrel of a microscope. Today the clinical utility of real-time ultrasound including Doppler, computerized tomographic scans, magnetic resonance imaging, and electron microscopy are all accepted as routine. Recent developments in MRS such as these described today will succeed ultimately in making it the youngest child in the family of imaging sciences.

Dr. Louis H. Weiland, Scottsdale, Arizona. Recognition of disease states in tissues have relied on microscopic examination for the past century and the usefulness of such methods is well recognized. However, with earlier detection of disease recognition of morphologic microscopic changes becomes diminishingly subtle. In recognition of this fact, the authors report on their attempt to recognize disease states of uterine tissues biochemically, by means of relatively new technology. Specifically, they have submitted uterine tissues to MRS with measurements of ^{31}P. Phosphorus exists within the cell as inorganic phosphorus and as many organic compounds composing metabolites and components of cell structure. Since this is a noninvasive (at a cellular level) technique, the specimens can be further submitted for histologic study. The early and very limited results suggest the possibility of quantitative differences in their measurements of diseased versus normal tissue.

A critical problem in MRS when performed in vitro is maintaining cells in their natural physiologic state. Endometrial tissue has a relatively high metabolic rate and it is questionable whether the authors were successful in maintaining this natural state with their stated techniques. The fact that the tissues appeared well preserved on histologic examination is not adequate proof that their physiologic processes were not significantly altered. Hopefully, this study will be an introduction to what might be an exciting and useful method of noninvasively examining cells and determining the presence (or absence) of a disease state.

Dr. Daniel A. Rightmire, Springfield, Illinois. Has the research team had the opportunity to examine specimens with electron microscopy in addition to light microscopy after MRS with their new probe?

Ms. Raman (Closing). It was indeed a great opportunity for me at this stage of my graduate career to realize the impact of this type of basic research and obtain feedback from clinicians who will use or exploit the potential of this new technique.

I must mention (and probably reiterate something that Dr. Quirk and Dr. Weiland mentioned) that MRS or even MRI of reproductive tissues had been neglected until the last few years. Although the very first clinical study was by Odeblad, who himself was a Swedish obstetrician and gynecologist, no one studied these tissues until the 1980s when Professor Dawson studied the effects of pregnancy on the rat uterus. Therefore it is indeed encouraging to see that additional research is developing in this area. It is probably quite likely that there will be a tremendous growth of applications of MRS to the specific field of obstetrics and gynecology.

Dr. Quirk raised the question of absolute calibration. In this stage of our study, we did not want to obtain

absolute quantities of substances (i.e., we did not want to say there were so many millimoles of phosphomonoesters in this tissue versus that), primarily because absolute calibration takes longer than the rapid pulsing that we now utilize. Since we are comparing the same ratios for the normals and controls, those are not variable, and therefore there is indeed a relative elevation of phosphomonoester intensity reported in this article.

The cost of obtaining biopsies by NMR was also questioned. If we assume that we have bought an NMR spectrometer, which is the main expense, on an hourly basis some outside collaborators are charged approximately $10 to $12 for an hour of experiments on this machine. We calculated that for the time needed for a biopsy experiment of about 6 hours, including all the costs of doing the biopsy, it is approximately $50, or slightly less, for one particular experiment.

That point was raised merely to suggest that even though MRI is currently a popular diagnostic tool, MRS should not be neglected because there is a definite savings, not only in cost, but we can also obtain a new perspective on the tissues under study.

What about the phosphomonoester peak? Can the individual phospholipids there be resolved? This was an interesting question because that is a question that I am pursuing currently. As you progress to a higher field strength magnet, the spectrum itself can expand so that other constituents of each peak are resolved and they can be observed individually. For instance, phosphomonoesters are basically phosphoryl choline and ethanolamine. You can see the individual peaks when you go to a higher field magnet, and you can get quantities of the particular compound that is causing that change in phosphomonoester. Extracts of the tissue should also be performed for identifying individual phosphomonoesters.

Dr. Weiland commented on MRI and MRS and compared them, and that was an interesting comparison. I must state that there have been reports earlier and as recently as a few months ago in a radiology article in which investigators studied bone and soft tissue lesions and performed biopsies on them; they could not obtain all the information from their proton imaging. They performed phosphorus nuclear magnetic resonance studies and were able to obtain a greater amount of information and thereby a better prognosis.

Dr. Weiland asked the question of why we are studying endometrium and myometrial tissues. We have done studies on nonpregnant and pregnant uteri. We have studied the placenta in the three trimesters, and have also looked at fallopian tubes and ovaries. As I mentioned, this is just one aspect of my project involving myometrial and endometrial tissues; I am trying to realize the application of MRS to the entire field of reproductive tissues.

With regard to preserving the tissue in a physiologic solution, phosphorus spectroscopy itself is used to study whether a tissue has been preserved or not. There are several groups that are studying the viability of placentas after they are removed and are trying to do experiments on them. One group of researchers is trying to determine whether the placenta can be maintained in a living condition once it is removed. There is proof that there is a comparison between the results of our isolated studies and the in vivo studies.

Only recently, at a conference in Amsterdam, a group from the United Kingdom reported the first in vivo studies of human placenta. Their spectra compare well with our spectra. Therefore, once we know the actual amount of adenosine triphosphate that should be present in the placenta or in these tissues and if we can maintain those same high levels during experimentation, we can be fairly sure that the tissue is biochemically well preserved.

Dr. Weiland discussed other kinds of nuclei that can be exploited. Currently, phosphorus is very popular for studies of living systems because it provides a direct insight into the metabolic processes since adenosine triphosphate is a phosphorus compound and the other membrane constituents are phosphorus compounds.

In conclusion, I am encouraged by the feedback I have received from this forum; it is indicative of the fact that my initial work will probably be fruitful if such encouragment is sustained.

The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: A prospective blinded study

Dev Maulik, MD, PhD, Prasad Yarlagadda, PhD, James P. Youngblood, MD, and Pamela Ciston, RDMS

Kansas City, Missouri

This prospective blinded study investigated the diagnostic efficacy of the umbilical arterial systolic/diastolic ratio performed at 34 to 36 weeks' gestation for identifying pregnancies at a high risk for adverse perinatal outcomes. A series of 350 consecutive singleton pregnancies were included in the study. A continuous-wave Doppler instrument with a 4 MHz transducer was used. The criteria for an abnormal perinatal outcome included intrauterine growth retardation, an Apgar score of <7 at 5 minutes, umbilical arterial pH at birth <7.20, presence of thick meconium, fetal distress in labor, and neonatal complications necessitating admission to the neonatal intensive care nursery. The analytic techniques included determination of the receiver operating characteristic curve, sensitivity, specificity, positive and negative predictive values, and the kappa index. The results demonstrated that although the cutoff value of 2.9 showed the maximum inherent discriminatory power, its diagnostic efficacy (sensitivity, 0.83; specificity, 0.87 positive predictive value, 0.74; negative predictive value, 0.92; and kappa index, 0.68) was not substantially different from that of the more common cutoff value of 3.0 (sensitivity, 0.79; specificity, 0.93; positive predictive value, 0.83; negative predictive value, 0.91; and kappa index, 0.73). Both values were rated good to excellent by the kappa index. The study also demonstrated that the systolic/diastolic ratio was a better predictor of general abnormal outcome than of the suboptimal fetal growth. (AM J OBSTET GYNECOL 1990;162:1518-25.)

Key words: Doppler, systolic/diastolic ratio, abnormal outcome, diagnostic efficacy

Recent experience suggests that the Doppler velocimetry of the umbilical arterial flow can be of potential benefit as a fetal surveillance tool. However, any such use of the Doppler technique requires (1) an understanding of the various factors that contribute toward its variance, (2) an unbiased demonstration of its diagnostic efficacy, and (3) a randomized clinical trial to demonstrate that the use of the technique leads to an improved perinatal outcome. Previously, we defined some of the factors that influence the variability of the Doppler indices measured in the umbilical artery.[1] In this component of our ongoing project, we present our results from a prospective blinded study that investigated the diagnostic efficacy of umbilical arterial Doppler ultrasonography in the last trimester of pregnancy as a screening test for identifying high-risk fetuses. Specifically, the investigation aimed to assess the inherent discriminatory ability and diagnostic accuracy of various cutoff values of the umbilical arterial systolic/diastolic ratio measured at 34 to 36 weeks' gestation in identifying those pregnancies that are at high risk for an adverse perinatal outcome.

Methods and material

The patient population consisted of a series of 350 consecutive singleton pregnancies at 34 to 36 weeks' gestation. Most patients were medically indigent. The investigation was conducted with the approval of the Institutional Review Board and informed consent was obtained. Each patient had a single Doppler examination that was performed with a continuous-wave instrument with a 4 MHz transducer (Multigon, Inc., Vernon, N.Y.). The method of examination has been described previously.[2] The results of the examination were not made available for clinical management. The perinatal outcome was considered abnormal when any one or combination of the following parameters was present: small-for-gestational age (SGA, <10th percentile), an Apgar score <7 at 5 minutes, umbilical arterial pH at birth <7.20, presence of thick meconium, fetal distress in labor (late decelerations, severe variable decelerations, absence of variability, fetal scalp pH <7.20),

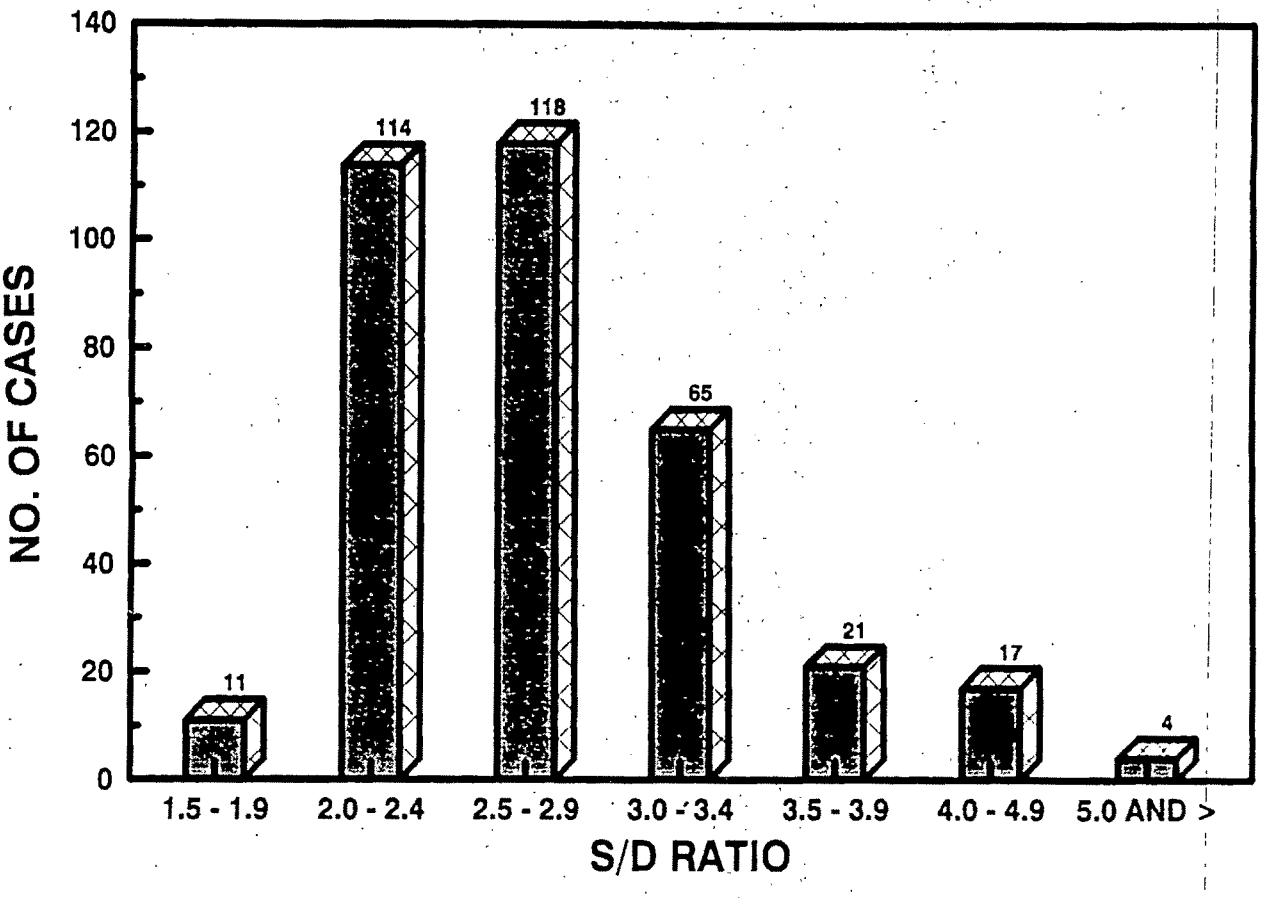

Fig. 1. The distribution of the umbilical arterial systolic/diastolic ratio in the study population. Note its non-Gaussian distribution.

and neonatal complications necessitating admission to the neonatal intensive care nursery.

To determine the optimal value of systolic/diastolic ratio for identifying the fetus at risk, the probability density distribution of the systolic/diastolic ratio among the normal and abnormal outcome groups and the receiver operating characteristic analytic technique, described by Weinstein et al.,[3,4] were used. The receiver operating characteristic technique offers a powerful tool for determining the inherent discriminative power of a clinical test.[3,4] The receiver operating characteristic curve graphically depicts the changes in the true-positive rate and the false-positive rate with respect to one another in relation to a series of cutoff points of the test value. The point closest to the upper left corner of the graph (depicting the cutoff value with the maximum true-positive and minimum false-positive rates) represents the greatest intrinsic ability of the test to discriminate between normal and abnormal population groups. This curve thus assists in selecting the test value best suited to separate those who are at high risk from those who are at low risk. The performance of the test at the selected value was expressed in terms of sensitivity, specificity, and the positive and negative predictive values. Finally, the extent of agreement between the test results and the outcomes, that could not be attributable to chance, were assessed using Cohen's kappa index[5] according to the method of Fleiss.[6]

Table I. Distribution of abnormal outcome cases

	No. of cases	*%*
SGA (weight <10th percentile)	43	39.4
Apgar at 5 minutes <7	9	8.3
Umbilical artery pH <7.2	13	11.9
Fetal distress	36	33.0
Meconium	52	47.7
Neonatal intensive care unit admission	5	4.6
Total abnormal outcomes	109*	

*An individual case might have one or more abnormal outcomes.

Results

Of the 350 cases, 109 (28%) pregnancies culminated in adverse outcomes. The distribution of various ad-

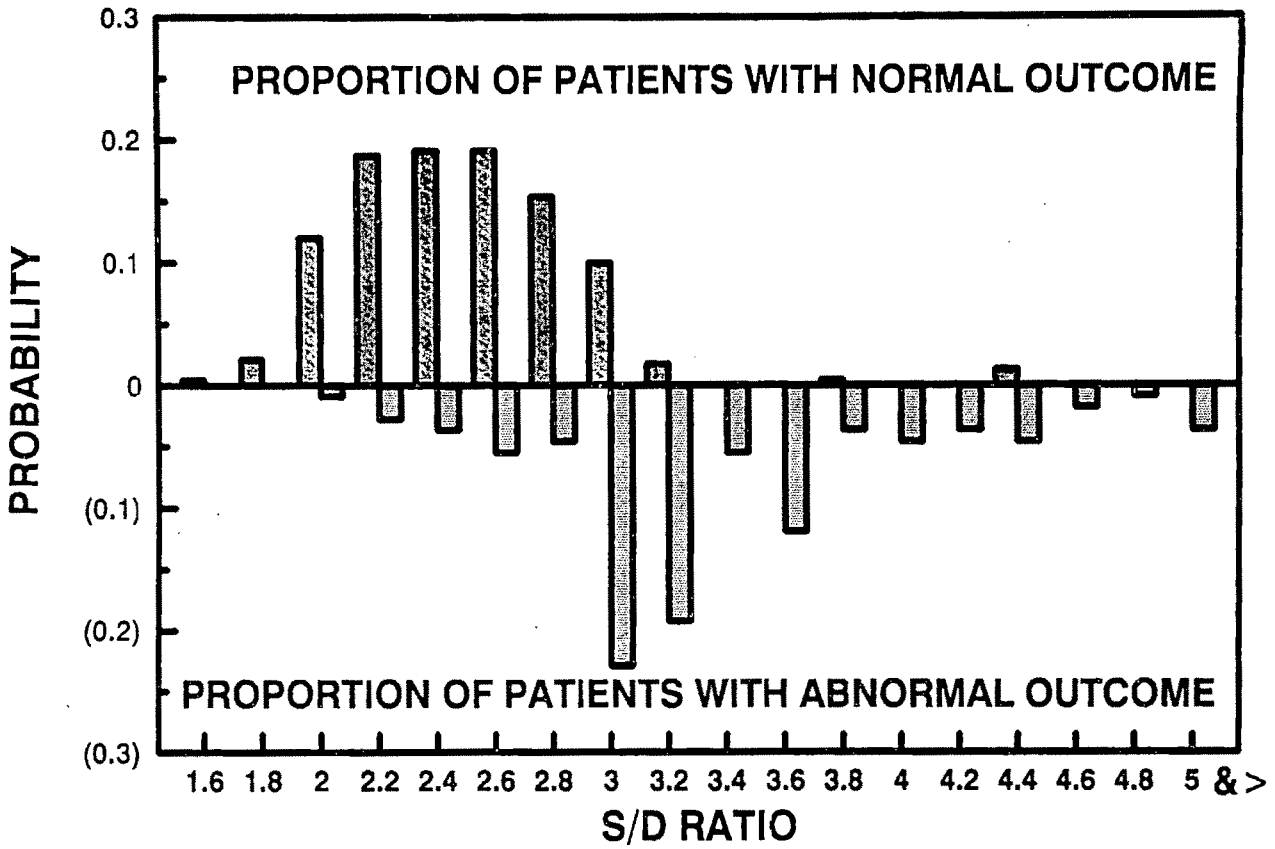

Fig. 2. The distribution of the umbilical arterial systolic/diastolic ratio among patients with and without normal perinatal outcome. Each vertical bar above the zero line represents the proportion of the total normal patients at a given systolic/diastolic ratio value; the *bars* below the zero line represent the same in the abnormal population. Note that the systolic/diastolic ratio cutoff values are capable of discriminating the patients with differing probabilities of normal and abnormal perinatal outcomes. However, no cutoff value designates all patients with adverse outcome as test positive without falsely categorizing some patients with normal outcome as test positive.

Table II. Test performance values for various systolic/diastolic ratio cutoff points

Cutoff point	*Sensitivity*	*Specificity*	*Positive predictive value*	*Negative predictive value*	*Kappa index*
2.5	0.93	0.53	0.47	0.94	0.36
2.9	0.83	0.87	0.74	0.92	0.68
3.0	0.79	0.93	0.83	0.91	0.73
3.5	0.35	0.99	0.93	0.77	0.41

Table III. Diagnostic efficacy of systolic/diastolic ratio cutoff point of 3.0 to predict the various abnormal outcomes

Category	*Sensitivity*	*Specificity*	*Positive predictive value*	*Negative predictive value*	*Kappa index*
General abnormal outcome	0.79	0.93	0.83	0.91	0.73
SGA only	0.75	0.77	0.32	0.95	0.33
FD, Apgar, pH, NICU	0.86	0.88	0.68	0.96	0.69
FD, Apgar, pH, NICU, and meconium	0.82	0.92	0.81	0.92	0.74

FD, Fetal distress; *NICU,* neonatal intensive care unit admission.

verse outcome parameters is shown in Table I. It should be noted that an individual pregnancy might have more than one abnormal outcome. In the normal outcome group, the mean (±SD) birth weight and gestational age were 3295.5 (±475) gm and 39.1 (±1.5) weeks, respectively; in the abnormal group, the corresponding figures were 2817.3 ± gm and 38.0 (±2.3) weeks, respectively. The cesarean section rates for the normal and the abnormal groups were 17% (43/241) and 35% (38/109), respectively. Fig. 1 depicts the frequency distribution of the systolic/diastolic ratio. As expected, this distribution was not Gaussian. The probability density distribution of systolic/diastolic ratio among patients with normal and abnormal perinatal outcomes are shown in Fig. 2. The graph shows the separation of these two patient populations at different values of systolic/diastolic ratios; each bar at a given value of systolic/diastolic ratio represents the proportion of the total group (normal or abnormal) at that value. The receiver operating characteristic curve of the systolic/diastolic ratio is depicted in Fig. 3. By evaluating the various cutoff points of the systolic/diastolic ratio, it was apparent that the value of 2.9, and not 3.0, offered the best inherent discriminatory power. The diagnostic efficacy of systolic/diastolic ratio values of 2.5, 2.9, 3.0, and 3.5 were then further assessed by estimating the corresponding specificity, sensitivity, positive predictive value, negative predictive value, and kappa index (Table II). The results demonstrated that in the study population, an systolic/diastolic ratio cutoff point of 2.9 rather than 3.0 offered a better sensitivity but a lesser specificity and positive predictive value in regard to predicting the overall adverse perinatal outcome. According to the recommended interpretation of kappa index,[7] both 2.9 and 3.0 fared as good to excellent tests, and 2.5 and 3.5 as poor tests. The diagnostic efficacy of the systolic/diastolic ratios of 2.9 and 3.0 were then further analyzed in relation to the following subgroups of adverse perinatal outcomes: SGA only; intrapartum fetal distress, Apgar score <7 at 5 minutes, umbilical arterial pH below 7.20, and neonatal intensive care unit admission; and the latter outcomes combined with the presence of significant meconium (Tables III and IV). This analysis indicated that the systolic/diastolic ratio at both the cutoff values was a better predictor of general adverse perinatal outcome than of the suboptimal fetal growth.

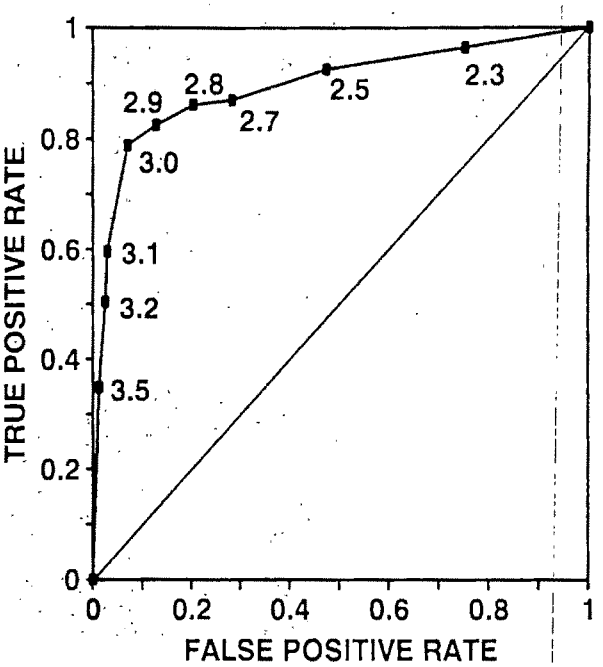

Fig. 3. Receiver operative characteristic curve of the umbilical arterial systolic/diastolic ratio. Note the systolic/diastolic ratio cutoff point (2.9) closest to the upper left corner of the graph possesses the best ability to discriminate between the normal and abnormal perinatal outcome groups.

Comment

Antepartum recognition of pregnancies with an elevated risk of adverse perinatal outcome continues to be a major challenge in obstetric practice. A significant proportion of infants who are recognized as being at low risk by the existing criteria of risk assessment experience a compromised outcome. Existing fetal monitoring techniques are only used in pregnancies already identified as high risk. Currently, maternal assessment of fetal movement on a daily basis offers the only screening tool for all pregnancies. It is in this context that the need to explore the potential of umbilical arterial Doppler velocimetry as a screening tool can be appreciated, especially because this test can be performed simply and readily with a relatively inexpensive continuous-wave Doppler device.

Earlier studies had established the feasibility of using Doppler ultrasonographic technology in assessing blood flow velocity in the umbilical artery.[8-10] Subsequent experience demonstrated a significant association between an abnormal Doppler index and pregnancy complications.[11, 12] More recently several preliminary studies have indicated that the umbilical arterial Doppler velocimetry can be a powerful predictor of an adverse perinatal outcome.[13-15]

Consistent with the principles stated previously for the essential evaluatory steps in developing a diagnostic test, this component of our ongoing project aimed to assess comprehensively not only the diagnostic efficacy, but also the various cutoff points of the systolic/diastolic ratio. The latter is a critical component of the assessment process since the diagnostic efficacy of the test is also dependent on the choice of the cutoff point. In this regard the probability distribution graph of the normal and abnormal outcomes at the various sys-

Table IV. Diagnostic efficacy of systolic/diastolic ratio cutoff point of 2.9 to predict the various abnormal outcomes

Category	*Sensitivity*	*Specificity*	*Positive predictive value*	*Negative predictive value*	*Kappa index*
General abnormal outcome	0.83	0.87	0.74	0.92	0.68
SGA only	0.75	0.71	0.27	0.95	0.23
FD, Apgar, pH, NICU	0.86	0.82	0.60	0.96	0.56

FD, Fetal distress; *NICU*, neonatal intensive care unit admission.

tolic/diastolic ratio cutoff points (Fig. 2) and the receiver operating characteristic curve (Fig. 3) immensely facilitated an objective determination of the most appropriate test value. Subsequent assessment of the test value was assisted by the determination of not only the traditional parameters such as the sensitivity, specificity, and positive and negative predictive values, but also the kappa index.

It should be noted that our study population with a 30% abnormal perinatal outcome cannot be considered a low-risk general obstetric population. This is not surprising because most patients were medically indigent and therefore were at high risk for a multiplicity of medical and social problems. Given this specific population background, our investigation suggests that extreme values such as 2.5 and 3.5 may not be suitable for clinical application. Furthermore, the cutoff values of 2.9 and 3.0 demonstrated impressive diagnostic efficacy. However, the commonly used cutoff value of 3.0 demonstrated a higher specificity, positive predictive value, and kappa index than those related to the value of 2.9. In view of the inherent imprecision of the method as demonstrated by the interobserver and intraobserver variations,[1] such apparently subtle differences in the cutoff point may not be clinically meaningful. It was interesting to note that the ability of the systolic/diastolic ratio (at cutoff values of 2.9 and 3.0) to predict only SGA was inferior to its ability to predict other adverse outcome parameters. Exclusion of the presence of thick meconium as an adverse outcome parameter improved sensitivity, but reduced the specificity, positive predictive value, and the kappa index.

In the final analysis the choice of the systolic/diastolic ratio cutoff point should consider the prevalence of the disease and other factors contributing toward its probability of occurrence before the test; thus in a low-risk population with a lower prior probability of abnormal outcomes, this test threshhold value will not demonstrate the same degree of high predictive value. In selecting the cutoff values, it would also be necessary to consider the consequences of a false-positive diagnosis against those of a false-negative diagnosis, particularly in regard to the use of the test as a screening tool as opposed to its use as a confirmatory diagnostic method. Furthermore, any comprehensive clinical assessment of the umbilical arterial Doppler velocimetry should encompass evaluating the relative merits of the various techniques of waveform analysis, and testing their diagnostic efficacy in conjunction with the existing standards of practice for fetal surveillance.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. Kathryn L. Reed, Tucson, Arizona. The extended abstract and additional tables by Maulik and colleagues detail one of the largest reported series of patients examined with Doppler ultrasonography during pregnancy. I would like to focus on three aspects of the study.

First, what does the umbilical artery waveform measure? We know that blood flow in the fetus results from a complex interaction of pressure changes, volume flow, heart rate, resistance, vessel wall elasticity, vessel size and shape, ventricular function, and blood viscosity. Thompson has stated that there is not a physical entity that can be measured that corresponds to the blood velocity waveform.[1] However, it is important to outline the various physical factors that influence the waveform, and to perform experiments in which these factors are varied.

In addition to the sources of physiologic variability, there is also potential variation in the measurement of the waveform itself. Estimates of error inherent in the waveform measurement range from 4% to 10%.[2,3] This amount of error would make the distinction between 2.9 and 3.0 clinically irrelevant.

Second, why were the particular end points chosen with which the changes in Doppler waveforms are compared? Endpoints are notoriously elusive and difficult to quantitate, and several investigators have battled with the concept. Perinatal mortality is uncommon enough (8/1000 live births[3]) that studies in many patients are required to show improvement. For this reason, outcome variables are often directed toward measures of morbidity, particularly asphyxia. These endpoints, however, are also somewhat elusive. The definition of intrauterine growth retardation varies by geographic location; furthermore, not all fetuses with small size are abnormal.[4] An Apgar score of <7 at 5 minutes does not correlate with long-range outcome.[5] Asphyxia probably does not occur above a pH of 7.20[5] and after a normal birth the umbilical artery pH is 7.28 ± 0.05 (range, 7.15 to 7.43,[7] thus the value used in this study is actually in the normal range. Presence of meconium may or may not be associated with adverse fetal outcome; in one study 1% of neonates with meconium had true acidemia.[6] The definition of fetal distress may vary with examiner; 16% of those delivered for fetal distress had severe acidosis (umbilical artery pH <7.12) in a report by Sykes et al.[8] Admission to the neonatal intensive care unit may be more a result of the prematurity of the neonate than hypoxia or asphyxia. At times birth events may alter fetal state from

normal to abnormal. It would be unlikely that a single common pathway ("placental resistance") would account for the morbidity seen at birth.

Finally, several other investigators have reported similar studies. Table I lists nine of these studies.[9-17] The studies varied in terms of definitions of morbidity and ratio cutoff points; sensitivities ranged from 45% to 79%.

I will close with several questions for Dr. Maulik. (1) What do you think the velocity waveform measures? (2) How do you explain the association between the waveforms and the outcome variables you chose to measure? and (3) Can you explain the wide variation in results reported in other studies of umbilical blood flow velocity in pregnancy?

Dr. Daniel A. Rightmire, Springfield, Illinois. I would like to ask Dr. Maulik what the interval was from the time of systolic/diastolic measurement to delivery in the normal and abnormal outcome pregnancies. By testing at 36 weeks, many of the very high-risk pregnancies may have been eliminated from consideration.

The authors' use of the frequency distribution curve format for presentation of their data is highly informative. We see from Fig. 1 and Fig. 2 that the distribution curve for the systolic/diastolic ratio is non-Gaussian. The distribution curve for patients with an abnormal outcome is especially skewed. It is also considerably expanded compared with the curve for normal patients. Thus the authors were wise to use distribution-independent statistical techniques. Descriptive and inferential statistical techniques that depend on normally distributed data and equal variances in tested populations such as *t* tests, certain analyses of variance, and linear regression techniques are inappropriate for use with systolic/diastolic ratios. The systolic/diastolic ratio can be corrected for nonnormality of the underlying distribution by transforming from the Pourcelot ratio values.[1,2]

Although the authors stress the different performance of systolic/diastolic at a cutoff of 2.9 versus 3.0, we are aware that with about 9% variability in the measurement technique, a value of 2.9 is probably indistinguishable from 3.0 when actual measurements are made. Test results such as 2.7, 3.0, and 3.3 might represent discernible steps with the continuous-wave Doppler technique.

In Table III the data are displayed that indicate that the systolic/diastolic ratio is not a particularly good predictor of a small fetus. This is not really unexpected because some fetuses are constitutionally small and do not suffer from a placental lesion or hypoxia.

Whereas the sensitivity and specificity of a test are properties of the test itself and of the outcome parameters chosen, the predictive value of a positive test is influenced greatly by the prevalence of disease in the study population. For a sensitivity of approximately 80% and a specificity of about 90% with a prior probability of 31% for an adverse outcome, the predictive value of a positive test will be approximately 70% to 80%. However, if the same test is used in a low-risk population with, for example, a prior probability of 5% to 10%, then the positive predictive value declines to approximately 30%.[3] Thus the performance of the systolic/diastolic ratio in a low-risk population has yet to be characterized and might be predicted to be rather poor.

Dr. Maulik has defined and studied the systolic/di-

astolic ratio as a test. He has characterized a cutoff value at about the 90th percentile of the normal population. However, I would like to ask Dr. Maulik if we should not consider the systolic/diastolic ratio as a test but rather as an examination. Are we not listening to the fetal umbilical circulation in an attempt to diagnose an underlying placental lesion definable histologically as an obliteration of medium-sized arteries?[4]

DR. JOHN A. GARBACIAK, JR., Phoenix, Arizona. Dr. Maulik, in your 350 patients, did you measure the umbilical blood flow at a specific point in the umbilical cord in all of these patients or did you measure it in a variety of places, placenta, fetus, and midcord? Are these values averages of those measurements?

DR. WASHINGTON HILL, Omaha, Nebraska. My question regard any information Dr. Maulik has with regard to a cutoff at an earlier gestational age, for example 30 weeks? Do you have any information you can share with us about that?

DR. MAULIK (Closing). Dr. Reed's question: "What does the Doppler index measure?" addresses a complex issue. The Doppler technique assesses the velocity waveform—this is the fundamental point. What controls the velocity waveform? Theoretically, both proximal and distal circulatory factors. Provided the central circulatory parameters such as the heart rate and cardiac contractility remain constant, the waveform reflects what is happening in the downstream circulation. There are studies (both in vitro and in vivo in animal models) that have correlated the waveform changes with the input impedance or the peripheral resistance of the downstream circulation. Obviously, in any interpretations of the Doppler indices, one needs to assume that the other factors in the circulation are constant.

In relation to the choice of the outcome parameters, I would like some guidance regarding what other kinds of morbidity parameters that we could choose. We do not claim any originality in our choice of these parameters. We followed the path taken by various investigators, such as those who had evaluated the nonstress test, contraction stress test, biophysical profile, and Doppler indices. This question has been debated, and I acknowledge freely that these are not perfect criteria.

Small for gestational age is probably a better terminology for what I described in the abstract as intrauterine growth retardation. That is why I presented this parameter in the paper as SGA. As pointed out by Dr. Rightmire, this condition is a "mixed bag." It is not surprising that the test did not predict SGA well.

We acknowledge that the presence of meconium is a soft criterion for adverse outcomes. We used our existing standard of practice, imperfect as it might be. The primary point is that in our experience, the inclusion or exclusion of this parameter did not make any difference in the results. In relation to the umbilical cord arterial pH threshhold value, I believe this was discussed previously in relation to another presentation. We abided by the current institutional standard. It is a controversial area, and 7.15 probably would be a better cutoff point.

I can only speculate in relation to variations in the reported specificity results. I believe the specific techniques used in the various studies may affect specificity. Moreover, population characteristics can certainly influence the variance. For example, characteristics of the patients enrolled in the Doppler study in Long Island would probably not be the same as patients we would encounter in Truman Medical Center, which serves the downtown indigent population.

I agree that the difference between the cutoff points of 2.9 and 3.0 is probably inconsequential given the error inherent in the technique. Actually, if we have to accept the validity of the kappa index, 3.0 is better than 2.9.

In relation to Dr. Rightmire's comments, he raises a philosophical question that I profess an inability to answer. We probably need to develop a test to differentiate between a test and an examination! Whatever we do with the patient ultimately translates into some kind of action. What practical difference does it make if we define this test as an examination or as a test? If you would recall, Dr. Schulman recently made a presentation on this isue. I believe that if the Doppler index is a test, let us call it a test, evaluate it as a test; and if it is indeed valid, then we should use it as a test. Otherwise, we should not.

In relation to the question of the applicability or validity of our results to an earlier gestational age, I think the results that we have are probably valid up to 28 to 30 weeks. Again, we have not presented here the results specifically in relation to earlier gestational ages, but on the basis of the published results and from our own experience, I believe we could use the same cutoff values up to 30 weeks' gestation.

With regard to the exact source from which we took these samples, we used a continuous-wave Doppler device and therefore used an inherently blind technique. That is probably the way we believe that this technique may be translated into a mass screening test. There are abundant data in the literature to demonstrate the validity of the continuous-wave Doppler approach. However, I would like to refer to our presentation at the Central Society meeting last year. The location of the measurement, specifically the abdominal end versus the placental end of the cord, can contribute 29% to 46% of the variance of the Doppler indices. Thank you.

Surgical management of breast disease in an obstetrics and gynecology group

James A. Hall, MD, Bernard R. Hall, MD, Duffy C. Murphy, MD, and Kyle A. Hall, RN, MSN

Logansport, Indiana

The surgical management of breast disease from 1978 through 1988 by the Women's Health Center of Logansport is reviewed. Three hundred twelve biopsy procedures resulted in the diagnosis of 59 cancers. Biopsy and mastectomy procedures were performed by the authors (obstetrician-gynecologists). There were no significant complications and all patients had an adequate surgical result. Preoperative needle localization techniques proved to be a safe and effective method to identify and remove nonpalpable mammographic abnormalities. Because women depend on their gynecologist for advice regarding reproductive organs including the breasts, it is logical for the gynecologic surgeon to become involved in the surgical management of breast disease. (AM J OBSTET GYNECOL 1990;162:1526-34.)

Key words: Breast disease, mammography

Breast cancer is the most common malignancy among women in most of Europe, North America, Latin America, and Australia. As many as one in 10 women in the United States may suffer from breast cancer during her lifetime. Breast cancer is also the second leading cause of cancer deaths in the United States, accounting for 18% of all female cancer deaths.[1] The obstetrician-gynecologist has a responsibility to patients to provide the latest and most accurate information regarding breast disease. Because the gynecologist holds the unique position as a primary care physician whom women consult with regard to breast disease and as a surgical specialist, the obstetrician-gynecologist can offer both diagnostic and definitive surgical treatment. Since early diagnosis is the key to breast cancer survival, the patient's primary care physician must aggressively search for early breast carcinomas. By participating in the management of the disease, the gynecologist will become a better diagnostician and better serve his or her patients. This article reports the surgical experience of an obstetric-gynecology group with breast disease from 1978 through 1988.

Material and methods

Two hundred and eighty-one patients seen from 1978 through 1988 had surgical procedures involving the breast performed by members of the Women's Health Center of Logansport. Author B. R. H. founded the practice in 1948; J. A. H. joined in 1978; and D. C. M. joined in 1982. B. R. H., J. A. H., and D. C. M. performed the biopsy procedures. B. R. H. and J. A. H. performed the mastectomy or breast conservation procedures. Mammography was provided by the local hospital radiology group and in most situations was reviewed by members of our group. Needle localizations before biopsy of abnormal mammographic areas were done by the radiology group. Training in breast surgery was gained either as part of residency training or by association with practicing breast surgeons. Patients were encouraged to have screening mammograms according to American Cancer Society guidelines.

Results

Three hundred and twelve biopsy procedures of 212 patients were performed; 157 involved the right breast and 155 involved the left breast. Sixteen bilateral procedures were performed. Of the patients who had operations because of a palpable mass, two thirds were detected initially by the patient and one third by the physician on screening examination. Two hundred and seventy-three of the procedures were done with the patient under general anesthesia and 31 with local anesthesia. Ninety-one needle localization biopsy procedures were performed for mammographic abnormalities. Of these 91 procedures, 62 were done for calcified abnormalities. In 61 of the 62 lesions with calcified abnormalities, specimen radiography confirmed the abnormal area had been removed with the initial biopsy attempt. One patient returned for a second excisional biopsy and the area was successfully removed. Confir-

mation of successful removal of noncalcified lesions (29 patients) was established in all patients by postbiopsy mammography. Therefore the rate of successful removal with the initial excisional biopsy for abnormal mammography was 99% (90 of 91 patients). Fifty patients who had operations for a mass also had a mammogram suggestive of malignancy. Thirty-three of these 50 biopsy procedures revealed carcinoma. One hundred eleven patients had operations for a mass and had a negative mammogram at the same time. Of these 111 patients, 11 had carcinoma in spite of their negative mammogram. The histologic findings of the biopsy specimens are revealed in Table I. There were 59 breast carcinomas confirmed by biopsy.

Table II shows the age distribution of patients undergoing breast biopsy procedures.

Table III provides year-by-year summation of the biopsy procedures. This table summarizes the percentage of biopsies with malignant histology for each indication during each year. Of 214 patients who had operations for breast mass, 50 (23%) had cancer. Nine of the 91 (10%) of the patients who had operations for mammographic abnormalities had cancer. However, since 1985 nine of 63 (14%) patients who had operations for mammographic abnormalities were found to have cancer. The fact that none of the mammographic abnormalities led to a diagnosis of breast cancer before 1985 is not totally unexpected because of the relatively recent use of the mammogram protocol procedures. As time progressed, both surgeons and radiologists gained confidence in what types of abnormalities should have biopsies performed. None of the patients who had biopsy specimens taken for pathologic nipple discharge in the absence of a mass have had carcinoma. Of all patients who had biopsies for any indication, 19% were found to have breast cancer.

Because patients diagnosed with cancer before the discovery of a mass have a better prognosis, the cancer patients have been divided into those discovered with a palpable mass and those discovered by mammographic abnormality alone (occult or T0 lesion). Of those cancers in the palpable mass group (50), there were 23 right breast cancers and 27 left breast cancers. The patient discoverd the mass in 37 of the 50 cancer patients, and in 13 the mass was found by the physician at the time of routine examination. Of the patients with breast cancer, some had other malignancies including prior breast cancer (three cases), lung cancer (one case), carcinoma in situ of the cervix (two cases), and adenocarcinoma of the endometrium (two cases). Only three of the 40 patients who had a recorded family history had a positive family history for breast cancer involving their mother or sister. Thirty-seven of the 50 patients with cancer with a palpable mass were initially seen with stage I cancer by the TNM method. Eight

Table I. Principal diagnosis of 312 breast biopsy procedures

Histologic findings	*No. of patients*
Fibrocystic disease	180
Cancer	59
Fibroadenoma	49
Sclerosing adenosis	12
Fibrosis	5
Intraductal papilloma	4
Fat necrosis	3

patients had stage II lesions, none had stage III disease, and one had stage IV cancer. Nine of the 50 patients with cancer with a palpable mass were gravida 0, two were gravida 1, and 39 were gravida 2 or more.

Table IV summarizes the status of lymph nodes as well as estrogen and progesterone receptors at the time of biopsy diagnosis for the palpable mass group and the group in which the cancer was suggested by mammographic abnormality alone. The palpable mass group has been subdivided into whether the patient or physician first discovered the mass. Of all patients with a palpable mass, 41% had malignant axillary nodes and 13% had four or more malignant nodes. Histologic features of the palpable cancer group revealed 45 ductal carcinomas, three medullary carcinomas, one ductal carcinoma in situ, and one inflammatory carcinoma. Treatment in this group primarily consisted of modified radical mastectomy. Eleven patients in this group received postoperative chemotherapy and 16 received hormonal treatment with tamoxifen. There were no significant surgical complications, such as excessive blood loss or infection. None of the patients required skin grafting. Two of the patients refused therapy and the axillary dissection was not done in two others. One of these patients had metastatic disease initially and died shortly thereafter. The other, more than 80 years old, had bilateral breast cancer with significant medical problems; unilateral modified radical mastectomy was done and segmental mastectomy was done on the opposite side. Of the 50 patients in the palpable cancer group, nine chose to have mastectomies performed by other surgeons. This number is not surprising because of the extreme emotional overlay of this disease. Patients with breast cancer often seek multiple physicians' opinions. The adequacy of the axillary dissection performed by members of our group compared with the patients who had operations elsewhere is documented by the fact that the nodal count of patients whose operations were performed elsewhere averaged 17 and the axillary nodal count of those whose operations were done by members of our group averaged 16 nodes removed.

Nine patients had breast cancer suggested by mammographic abnormality alone; four cases involved the

right breast and five involved the left breast. Eight of nine of these patients were gravida II or more and only one was gravida 0. Two of the nine patients had a positive family history for breast cancer and seven had no breast cancer in the family. All nine patients were first seen with a stage I T0 lesion (occult). After biopsy, surgical treatment consisted of modified radical mastectomy or segmental mastectomy, axillary node dissection, and radiotherapy. Malignant axillary nodal count is summarized in Table IV. Eight of the nine patients had negative nodes. One patient had two positive nodes. This patient was under 40 years of age and had a prior breast cancer on the contralateral side with known metastatic disease; however, she desired mastectomy. One patient's tumor was too small to measure hormone receptor volume. Two of the patients were treated with tamoxifen and two received chemotherapy. The pathology report revealed invasive ductal carcinoma in all nine patients. As with the group diagnosed with a palpable mass, patients often seek second opinions in response to the fear established by this disease. After biopsy, two of the nine patients with cancer had operations elsewhere; the number of axillary nodes removed averaged 11. The adequacy of the axillary dissection by members of our group was confirmed because the nodal count removed averaged 13.

Fifty-two of the fifty-nine patients with breast cancer, chose modified radical mastectomy, whereas three chose a conservation procedure of segmental mastectomy with axillary node dissection and radiotherapy. Four patients did not have a mastectomy or any definitive surgical therapy. As discussed previously, two of these patients refused therapy, thus attesting to the psychologic impact of this disease. One of the patients who refused therapy had metastatic disease that developed shortly thereafter and she died. Two patients were not treated because of metastatic disease or age and general medical condition.

Of all patients undergoing breast biopsy procedures by our group, none have had any significant complications. None of the patients had reoperations for complications and none had any significant infection. None of the mastectomy group had any significant complications. There have been no extended hospital stays, and the cosmetic results of surgery were satisfactory. None of the patients required postmastectomy skin grafting.

Comment

It has been documented by the results over the past 11 years that the obstetrician-gynecologist has the surgical expertise to manage breast disease. As practice

Table IV. Axillary node metastasis and hormone receptors related to cancer discovery

	Patient-discovered mass (No. of patients)	*Physician-discovered mass (No. of patients)*	*Abnormal mammogram (No. of patients)*
No. of malignant axillary nodes			
0	22	6	8

Estrogen positive, progesterone negative	4	1	2
Estrogen negative, progesterone positive	1	0	0
Total no. of patients with known receptor status	28	12	8

trends point to more breast conservation procedures, the surgical treatment becomes less complex. Radical mastectomy with complete axillary node dissection is no longer the standard of care. The number of breast cancers discovered over the past 11 years resulted from aggressive investigation for breast disease and encouraging patients to become involved in breast surveillance. None of the patients in this group had any significant complications. All patients who had operations for a palpable mass had the mass successfully removed with the initial biopsy procedure. Of the patients who had operations for mammographic abnormality with the aid of needle localization, 90 of the 91 (99%) had that abnormality removed with the first attempt. In the one patient who required second surgery, the needle placement was not in the area of the abnormality. In retrospect, this patient's abnormality represented a calcified area some years after a steering wheel injury to the pectoralis major muscle and the abnormality was not within the breast. However, this area was removed with the second needle localization attempt. This rate of successful biopsy of mammographic abnormal areas is compatible with studies by Ostrow et al.[2] and Leis et al.[3] These reports indicated that 2.7% and 2% of patients required a second excisional biopsy procedure to remove the abnormal mammographic area. Norton et al.[4] reported successful removal of the target lesion in 92% of patients who had general anesthesia and only 78% of patients whose biopsies were performed with use of local anesthesia. In this study over the past 4 years, 14% (nine of 63) biopsies for abnormal mammograms led to a diagnosis of cancer. This also is compatible with published reports by Ostrow et al.[2] (12.4%), Poole et al.[5] (14%), and Wright (9.8%). Leis et al.[3] and Schwartz et al.[7] have reported a higher rate of malignancy discovered from abnormal mammography at 38.2% and 32%, respectively. Eight of the nine patients with cancer suggested by abnormal mammogram alone had negative axillary nodes, and this is similar to the report by Rosenberg et al.,[8] who reported that all their patients with occult breast lesions had negative nodes. Poole et al.[5] reported that 17% of study patients with occult cancer discovered by mammography had axillary nodal metastasis. In contrast, 41% of those patients in this study whose cancer was initially detected as a palpable mass were found to have malignant axillary nodes and 13% had at least four malignant nodes.

The significance of receptor assays to prognosis has been somewhat controversial.[9] However, many feel that positive receptor status implies a better prognosis.[10] Of the patients whose breast cancer was discovered with a palpable mass, 40 had estrogen receptor studies performed. Fourteen of these 40 patients (35%) had negative estrogen receptors. In the group whose lesions were discovered by mammogram, two of the eight (25%) had negative estrogen receptors. In the palpable mass group, 18 of 40 (45%) patients had negative progesterone receptor assays and four of eight (50%) had negative progesterone receptors among the group with lesions discovered on mammogram. Although receptors status does not appear significantly different between the palpable mass group and the group with lesions detected by mammogram, it is noteworthy that the mammogram group had a much lower incidence of malignant axillary nodal involvement.

The numbers of patients in this report are too small to provide meaningful discussion with regard to outcome. Treatment protocols with chemotherapy have changed over the years. Thus it is not possible to compare patients and their survival. However, published reports indicate that patients with negative nodal status have a better chance of survival, as perhaps do those with positive estrogen and progesterone receptor assays. Thus it may be presumed that patients in this

group with diagnosis in an earlier stage of the disease with negative nodal involvement will have an improved chance of survival. In this report, 46 patients with cancer diagnosed with a palpable mass have recorded follow-up of 1 to 11 years. The majority of recurrences and deaths occurred within 5 years of the initial diagnosis. However, there was one patient who developed metastatic disease 9 years after mastectomy. Two of the patients died within 1 year of operation. There was additional death at 2 years. Two patients died at 3 years after operation and another died at 4 years. Thus six patients in the palpable mass group died of breast cancer within 5 years of diagnosis. Two patients also died of other causes and two had metastatic disease within 5 years and have been lost to follow-up. Nine of the 46 (20%) patients with follow-up and a palpable mass at diagnosis have died from the disease or have metastatic disease.

Of the patients whose disease was discovered by mammographic abnormalities, follow-up ranges from 1 to 4 years. None of those patients has had metastatic disease or has died of disease. One patient has died, but this is thought to be a result of the metastatic disease from the contralateral breast.

Patients whose breast cancer is diagnosed with a palpable mass have a worse prognosis and outcome than those suggested by mammographic abnormality alone. Leis et al.[3] reported a 10-year survival for those patients with occult lesions of 96.2% compared with 73% for those with stage I cancers and 43.1% for those with stage II cancers. Eleven patients with cancer were diagnosed with a palpable mass and had a negative mammogram concurrently. This emphasizes the absolute necessity of realizing that a mammogram is *not* a substitute for biopsy. It has been reported by Edeiken[11] that 22% of patients with palpable carcinoma had a negative mammogram, confirming the need to consider breast palpation and mammography as complementary procedures. It was also found that not all patients with a palpable mass suggested mammographically to be malignant actually had cancer. Family history proved to be of little prognostic significance because only five of 49 patients with breast cancer with recorded family history had a first-degree relative with breast cancer.

Breast cancer is a common malignancy with which the practicing obstetrician-gynecologist must become familiar. It is in the best interest of our patients that aggressive screening be used to ensure early diagnosis. Modified radical mastectomy and segmental mastectomy with axillary node dissection are within the surgical skills of the gynecologic surgeon. Our involvement in breast disease heightens both the patient's and our own awareness of the need for aggressive diagnostic screening. As more patients have mammographic examinations, increased numbers of abnormal areas will require biopsy procedures. It is not in our best interest to send our patients to others for biopsy procedures. Needle localization technique is safe and accurate and offers an excellent opportunity to adequately investigate mammographic abnormalities. Unfortunately, only approximately 10% to 15% of American women over the age of 50 have ever had a mammogram.[12] It is the responsibility of the obstetrician-gynecologist to encourage physicians and patients to use mammographic screening.

Three hundred and twelve biopsy procedures in this study resulted in the discovery of 59 breast carcinomas. Ninety-one biopsy procedures were for nonpalpable mammographic abnormalities leading to the discovery of nine breast cancers. None of the patients undergoing biopsy procedure or modified radical mastectomy by members of our group had a significant complication. Surgical management of breast disease is within the scope of expertise of the obstetrician-gynecologist and should be encouraged to better serve patients. Educational programs in breast surgery should be established.

Discussion

DR. RAYMOND A. LEE, Rochester, Minnesota. I wish to review this presentation from two different perspectives. From the scientific perspective, this study does not advance our knowledge of diagnosis, management, or the natural history of carcinoma of the breast. The anecdotal review of a relatively small number of patients, not prospectively randomized, seen

over a 10-year period does not lend itself to a statistical review nor can we make useful comment in evaluating the survival data. However, from the clinical perspective, it demonstrates that a small group of well-trained and conscientious physicians can provide excellent primary care for patients with breast disease.

Early breast carcinoma can be subtle and easily missed on examination, by mammography, or both, only to be blatantly obvious the following year when the patient has a distorted breast, obviously the result of malignancy which, in retrospect, could be identified on the prior mammogram. Some physicians may wish to perform the appropriate examination, obtain a mammogram, and refer all patients with any abnormality to a breast surgeon. Other physicians may wish to carry out the total care of the patient with breast disease. How this care can and should be provided will depend on the circumstances of the physician's local community.

If an abnormality is identified, the physician should have a thorough knowledge of breast disease, be able to choose the appropriate diagnostic procedures, and be familiar with the alternatives in managing the problem. If a definable mass is present, then a properly performed, appropriate aspiration or excisional biopsy procedure will readily lead to a diagnosis.

It is increasingly apparent that we are confronted with patients whose breast examination may be difficult. Abnormalities consisting of fine stippling of calcification or other radiologically identifiable masses require preoperative needle placement for accurate location to aid in and ensure appropriate resection. There are several aspects that have potential pitfalls under these circumstances: (1) proper placement of the incision to permit a satisfactory cosmetic result if the mass is benign and yet to permit wide local resection or mastectomy if required; (2) confirmation that the biopsy specimen includes the abnormality noted on examination or mammography (we prefer specimen radiography to compare with the preoperative mammogram); (3) certainty that there are no other abnormalities at the biopsy site.

The pathologist must be provided with the appropriate tissue. I personally leave the operating room with the specimen, filet the specimen myself, have the radiographs taken of the various portions of the specimen, compare these with the preoperative mammogram, and then carry the suspect tissue to the pathologist. Once the diagnosis is confirmed, the biopsy site can be closed or, if necessary, the appropriate operative procedure is performed. Modified radical mastectomy or the infrequently performed standard radical mastectomy is not a technically difficult operation.

Contrary to the authors' opinion, it is my impression that the judgment required in specific patients to ensure adequate removal of the malignant lesion and yet tailor the operative procedure to produce a cosmetically acceptable breast that will lend itself to radiation treatment can be quite difficult. At least in my experience, I find that the ever-increasing number of small lesions makes it increasingly difficult to obtain the appropriate tissue specimen. Furthermore, it is imperative that we select properly the patients who will have wide local excision and axillary dissection to be followed by radiation therapy. Other patients should have a subcutaneous mastectomy, unilateral or bilateral, with immediate or delayed implants inserted as the management of their problem. Modified radical mastectomy continues to be a very important operative approach in another selected group of patients.

My point is that there is no single operation that is appropriate for all patients; instead, we need to tailor our procedure to the specific circumstances of a specific patient.

I think we can offer excellent primary care of the breast for our patients. However, with the current technical advancements the best results will be obtained when there is a coordinated team effort as has been reported in this study.

Dr. Bruce H. Drukker, East Lansing, Michigan. This study from the Women's Health Center of Logansport, Indiana, is a superb contribution to the practical gynecologic literature. It clearly demonstrates that the gynecologist not only should be involved in the care of patients with breast disease but can complete this obligation with excellence. This experience with 281 patients over a 10-year period is significant. The shrouds of "turfism" or "turf battles" were swept away and physicians were able to provide quality continuity of care for their patients. By taking the initiative and following an accepted guideline, the authors have clearly demonstrated that gynecologists, when appropriately trained, can care competently for the breast problems of their patients.

This substantial experience has demonstrated a few salient points. First, that cancer found in a palpable mass has a more severe prognosis than that diagnosed by mammography without a palpable mass. In this report 41% of patients with a palpable mass diagnosed as carcinoma had positive axillary nodes at the time of diagnosis when compared with only 12% of patients who had positive axillary nodes when a carcinoma was diagnosed only by mammographic screening. Second, an additional support of improved outcome is the observation that no patients with a mammographic diagnosis of carcinoma confirmed by biopsy and subsequently treated have had a recurrence when followed up for 1 to 4 years. This is compared with nine of 46 patients who had a palpable mass diagnosed as cancer who died or have known metastatic disease during a similar follow-up. It is important to note, however, that metastases from breast carcinoma occasionally appear later than 10 years after the initial diagnosis, but the authors clearly demonstrate that at least to date the majority of recurrences have occurred within 5 years.

Perhaps we should state that we *expect* these very positive findings. If you concur, then you also commit yourself to mandatory mammography for your patients in compliance with American College of Obstetricians and Gynecologists guidelines.

Aside from these obvious successes, however, we must examine some areas that need clarification and are of interest to us all. First, how did the group members of this practice achieve their training? Were they fortunate enough to have exposure to treatment of both benign and malignant disease of the breast in their obstetric and gynecologic residency or did they take additional formal breast training with a surgeon after completion of a residency? Perhaps the surgical exposure was more of a "preceptorship." This is a very practical question for all of us; as we look to the future and become more involved with treatment of breast disease, training is a problem. Not infrequently do I receive queries from obstetrician-gynecologists asking, "How can I learn more about surgical treatment of breast disease?" Such opportunities for obstetrician-gynecologists in the United States are quite limited. The interdigitation of this learning opportunity in residencies in obstetrics and gynecology is of extreme importance.

From a purely technical position, we should note that only 11% of the biopsy procedures were done with use of local anesthesia. Surgeons are touting the benefits of local anesthesia, the ease of the procedure, the cost-effectiveness, and the lack of inconvenience for the patient. Nevertheless, the authors suggest that the accuracy of initial biopsy is compromised by local anesthesia and they clearly quote references that suggest that the accuracy is higher when general anesthesia is used. Could the authors tell us how they discriminate with respect to the type of anesthesia they elect? This obviously has very practical implications.

The authors also fail to provide us with a critical assessment factor, which impacts all physicians involved with or making recommendations based on mammographic assessment. The question is: which nonpalpable calcifications should have biopsy and which can be followed? The authors essentially described 62 patients with calcified abnormalities who had biopsy procedures, but I could not locate a figure that stated how many of these 62 patients had a carcinoma. Radiologists have suggested that one in six or seven biopsy specimens taken because of calcifications should be malignant. If that were so, then we would expect that eight or nine patients in this group would have had malignancy diagnosed on the basis of calcification pattern alone. If the number of positive diagnoses were high, for example, 12 to 15, it would reflect a very high level of radiologic discrimination of calcifications. Conversely, if it were only two or three, this would suggest a high rate of radiologic "overcall." It is necessary to consider the impact of unnecessary biopsy procedures on the cost of medicine in general. This is a sensitive issue and one where debate, I am sure, will be ongoing for a number of years. Table III attempts to partially answer the question but does not clarify whether the abnormal mammogram included only those patients with calcifications or also those with nonpalpable or palpable masses that were interpreted to be abnormal on mammographic assessment. Clarification of this important point would be helpful.

Despite these questions, this paper clearly reconfirms that mammography is the keystone to early diagnosis of breast cancer. Although the authors report only 91 of 312 biopsy procedures done for mammographic abnormalities during the period, I would predict that the next decade will show a significant increase from the present 29% to perhaps 60% to 70% that require biopsy based on only mammographic abnormalities. This will represent a dramatic improvement and will be brought about by increasing compliance of patients with respect to obtaining mammography, increasing availability, decreasing cost, and superior mammographic technology and interpretation.

This study should clearly demonstrate the success of gynecologists and obstetricians in screening and treatment of breast cancer. I congratulate the authors for a very significant contribution.

Dr. Maurice J. Mueller, Crescent Springs, Kentucky. This article does show that gynecologists can manage breast disease, but I feel that many of us are reluctant to become involved in management of breast tumors because of the legal ramifications. It seems to add one more legally risky procedure to the other risky things that we do in our practice.

Dr. Louis Weinstein, Tucson, Arizona. Dr. Hall, have you noticed changes in breast density in mammograms of patients on a regimen of hormonal therapy? Also, a simple question, in a patient who is ≥ 3 years after the diagnosis of breast cancer with no evidence of recurrence, would you treat her with hormonal therapy if she has symptoms?

Dr. Eduard Eichner, Cleveland, Ohio. I would just like to make a comment from the "old days." I used to do biopsies of all these lesions in the office routinely without mammograms because the radiologists were just learning to do mammograms and we could never depend on the reports they gave. I found that many of the areas I aspirated, except for cysts, ended up with a small deep hematoma and a mass that becomes very suspicious on a mammogram. Therefore, since that time, I get a mammogram first, except in the case of a cyst, because apparently, by using a big needle for suction, I was producing a little blood locally that changed the picture.

Dr. Robert W. Rebar, Cincinnati, Ohio. I just have some rhetorical and philosophical questions rather than questions directed toward the authors, who clearly demonstrated that they can in their circumstances care for this group of patients.

Originally I chose obstetrics and gynecology as a clearly demarcated field, and I thought it might be possible to continue to keep abreast of all the changes in it. As we expand into ever more areas in endocrinology, perinatology, and oncology, and now in breast disease, my question is how many of us can really keep on the forefront of the changes occurring in all these different areas?

I think that this becomes a question for me as a reproductive endocrinologist when I feel overwhelmed by some of the advances occurring in other parts of our specialty without going on to suggest that we now

become cognizant and aware of a whole new area of the literature that is found in a whole different set of journals.

Dr. Hall (Closing). I think, if I gave this presentation in front of the American College of Surgeons, I probably would need a helmet and a flak jacket. I thank you for your generosity.

I think Dr. Lee had excellent points to make, and I would like to expand on one. When we do a biopsy because of a calcified abnormality, we get specimen radiography with the patient still asleep on the table. We obtain an x-ray film of the specimen and then fillet it, as he mentioned. I then take the specimen to the pathologist and show him where in the specimen the abnormality is located. This is helpful to the pathologist because the specimen often is 3 or 4 cm but the area of abnormality may only be a couple of millimeters.

It's important to help the pathologist out—to say: "Here's the spot you've got to take. You can look at all of it, but here's the one spot in particular we don't want to miss."

Dr. Drukker asked about training. Again, I was fortunate enough to go into practice with someone who trained at a time when breast surgery was within the department of obstetrics and gynecology (and that's probably one that we let get away). A lot of my training was on the job from a good teacher, and I had some association with other breast surgeons.

I think, from a philosophical standpoint, for someone who has no surgical skills and who doesn't go in the operating room on a regular basis, it's probably not a good idea. We (gynecologists) are there everyday anyway. Our lockers are in the same room as the general surgeon's. We get the same scrub suits. I think, if we can open an abdomen, certainly we can handle some aspects of breast disease.

I think we'll be better diagnosticians of breast disease if we're involved in the disease. If a patient comes in the office and has a question about her breasts and you're a triage officer, you're probably not as good a clinician as if you were involved in the disease.

Regarding questions about how to decide on local or general anesthesia, the majority of these procedures have been done with local anesthesia recently. Initially, many were done with general anesthesia. The introduction to drugs such as Versed helped tremendously as far as doing these procedures under local anesthesia. In the mammographic abnormality group we used only general anesthesia because the literature supports that, and I agree.

The patients with mammographic abnormality but without a mass are best placed under general anesthesia because the radiologists don't want the patient to lie down and have the needle placed perpendicularly because they're afraid of hitting the lung. So the patient sits up and the radiologist puts the needle in from the top down. The patient is then taken to the operating room and lies down. The tip of the needle sometimes isn't close to where you think it is; if you make an incision and try to cut down and find the tip of the needle and it isn't there and the patient is squirming on the table and wanting to know what's wrong, sometimes, as Norton found in his study, you have to abandon the procedure. We've done all procedures in patients with mammographic abnormalities under general anesthesia and have had 100% successful removal. All procedures have been done on an outpatient basis.

In the group with a palpable mass, selection of anesthesia depends on the anxiety of the patient. I ask them how do you want to do this? I prefer local anesthesia, but we let the patient become involved in that decision.

Of the group with calcified abnormality versus those with mammogram abnormalities but no calcium, I believe 63 of the 91 patients had calcium within the mammographic abnormality. I think all of the cancers were in that group. Therefore there was a discovery rate of about 16% of calcified abnormalities on mammogram that ultimately proved to be malignant, and that's right in line with the literature.

One of the questioners asked about the legal ramifications. I would cite the other side of the coin. There is ample precedent in the courtroom of malpractice in not discovering breast cancers early enough. I think, by becoming involved in the disease, you're going to find these cancers earlier, give better service to the patient, and perhaps get the medical-legal noose off your neck rather than be a triage officer whereby the patient perhaps gets lost in the system and is sent to a physician she doesn't know or maybe doesn't have confidence in. The patients already know us. They already have confidence in us, and I think we're going to do them a service and perhaps stay out of the courtroom.

I don't have any data regarding hormone effects on mammograms. Mammography is probably best not done during the menses and immediately before the menses because the breasts are too tender for compression on the mammogram. Mammography is best done the week after the menstrual period when the radiologist can compress the breast, thus using less radiation, and get a better picture. The postmenopausal breast is probably not quite in the same situation, so it probably doesn't make a lot of difference.

I have medical oncology specialists see all of these patients, so I defer to their expertise, but I would be very hesitant in putting a patient who has had breast cancer on a regimen of estrogen.

Philosophically, about one more procedure to do and one more thing to keep up on is an interesting question, with turf fights and all of that. I don't have any great pearls of wisdom about that other than I think this is something we can do. I think it's something that we dabble in anyway because the patients come in for routine breast care. They come to us with their questions, and I think it's only in their best interests that we answer those questions the best way that we can. I think the best way we can answer those questions is to become involved in the management of the disease. I don't think that's beyond our capabilities.

As far as the turf fights, battle lines for turf have

been drawn and are being drawn in hospitals and by the American College of Surgeons, which is not very happy about the gynecologist's introduction into breast disease. I hope that when the "powers that be" in obstetrics and gynecology decide who's going to champion the fight for turf in our involvement in breast disease, doers and not talkers are picked.

I think we need people who are out there seeing patients, not necessarily those who are thinking about it or postulating how to treat patients. If you're in practice and seeing patients, my recommendations make sense. This plan can work, and I think we will be doing the patient a good service.

Evaluation of a continuous combined low-dose regimen of estrogen-progestin for treatment of the menopausal patient

Louis Weinstein, MD, Chhanda Bewtra, MB, BS, and J. Chris Gallagher, MD
Tucson, Arizona, and Omaha, Nebraska

Menopause constitutes a sizable proportion of the adult woman's life, and it is reasonable to consider that most women will benefit from hormone-replacement therapy. Also, it is important to realize that cardiovascular disease is a major cause of morbidity and death in the menopausal patient. Two regimens of hormone-replacement therapy were evaluated in postmenopausal women with 0.625 mg of conjugated equine estrogen with either 2.5 or 5 mg of medroxyprogesterone acetate taken continuously for 52 weeks in 92 patients. The data demonstrated an improvement in menopausal symptoms, a beneficial effect in lipoprotein profiles, the establishment of an atrophic endometrium, and a marked decrease in vaginal bleeding after 13 weeks and a further decrease after 26 weeks. Ideally this regimen will offer better patient compliance and, if the favorable lipoprotein profiles offer protection to the cardiovascular system, the overall health of the American woman will be markedly affected. (AM J OBSTET GYNECOL 1990;162: 1534-42.)

Key words: Estrogen, progestin, continuous low-dose regimen

As the population continues to age, more medical attention is being directed to quality-of-life issues. It has been reported that 90% of women live to reach menopause, with an average life expectancy of 28 years after menopause.[1] This means that the practitioner seeing female patients must have an understanding of the physiologic changes of menopause and what pharmacologic treatment is indicated.

During more than half of the average woman's life, she has the intrinsic production of hormones such as estrogen and progesterone that offer protection from cardiovascular disease and osteoporosis. After menopause the immunity from coronary artery disease and osteoporosis is lost.[2, 3] It is critical to appreciate that coronary artery disease has four times the death rate in women as breast and endometrial cancer combined.[4]

The use of estrogens for the postmenopausal patient can prevent vasomotor symptoms and urogenital atrophy and offer protection from osteoporosis.[5] If a regimen of drug administration could be determined that would offer the listed benefits, as well as protect the endometrium from carcinoma, have high patient compliance, have minimal vaginal bleeding, and alter lipid profiles favorably to decrease the risk from cardiovascular disease, the overall health of women would be vastly improved.

The regimen of a continuous low-dose estrogen-progestin combination appears to offer more benefits to the patient than does the standard sequential administration of hormones.[6] This study was devised to evaluate further a continuous regimen of 0.625 mg of

conjugated equine estrogen with two dosages (2.5 and 5 mg) of medroxyprogesterone acetate for 52 weeks.

Patients and methods

The total population consisted of 92 women who had been menopausal for at least 1 year, had serum estradiol and follicle-stimulating hormone levels in the menopausal range, and had not received any oral estrogen or progestin for the previous month or an injectable sex hormone for the past year. The study group was not controlled for diet, alcohol use, or smoking.

After being given proper informed, written consent approved by the Human Subjects Committee of the University of Arizona and Creighton University, patients were randomly assigned from a computer-generated list of numbers to one of two treatment groups. All patients received 0.625 mg of conjugated equine estrogen (Premarin; Wyeth Ayerst, New York, N.Y.) continuously, with group I (46 patients) receiving 2.5 mg of medroxyprogesterone acetate (Provera; The Upjohn Co., Kalamazoo, Mich.) and group II (46 patients) receiving 5 mg of medroxyprogesterone acetate. Total time for the study was 52 weeks, and the treatment groups were known to the investigators.

A medical history was obtained and a complete physical and pelvic examination was performed at the initial visit. A Papanicolaou smear and endometrial biopsy were done. The endometrial histologic findings were evaluated at each individual institution. A mammogram and urinalysis were obtained. Blood work included a complete blood count, fasting serum glucose, fasting lipoprotein profile (cholesterol, triglycerides, high-density lipoproteins plus subfractions 2 and 3, low-density lipoproteins, and very-low-density lipoproteins), liver function tests, creatinine, follicle-stimulating hormone, and estradiol.

After evaluation of the baseline studies, the patients were randomly assigned by a computer-generated list of numbers to either study group. All patients were instructed in maintaining a daily diary to record any vaginal bleeding, vasomotor symptoms, or side effects.

At the end of 3 months, the patient returned for an abbreviated physical examination, diary evaluation, and repeat fasting lipoprotein profile. The same occurred at 6 months with the addition of a complete blood count, liver function tests, and fasting glucose test. The 9-month visit was identical to the 3-month visit. The 12-month visit was the same as the baseline visit, which included a complete physical and pelvic examination, mammogram, blood work including fasting lipoprotein profile, and endometrial biopsy.

Women excluded from the study were those with a hypersensitivity to either hormone preparation, abnormal endometrial biopsy or papanicolaou smear, pelvic disease, history of gynecologic cancer, hypertension, hepatic, renal, or cardiovascular disease, history of thromboembolic disease, and type I diabetes mellitus.

Serum levels of follicle-stimulating hormone and estradiol were measured with commercially available radioimmunoassay kits.

The enzymatic procedures of Allain et al.[7] and Megraw et al.[8] were used to determine total serum levels of cholesterol and triglycerides, respectively. The high-density lipoprotein cholesterol fraction was measured by a rapid-precipitation technique with a combined equal-volume mixture of 2 mol/L magnesium chloride and dextran sulfate: 0.1 ml of precipitating reagent was added to 1 ml of serum, mixed, incubated at room temperature for 10 minutes, and centrifuged for 20 minutes. A modification of the total cholesterol method was used to assay the clear supernatant for high-density lipoprotein cholesterol.[9] Low-density lipoprotein cholesterol levels were determined according to the formula of Friedewald et al.[9]: low-density lipoprotein = total cholesterol − high-density lipoprotein − 1/5 triglycerides. Very low–density lipoprotein cholesterol levels were determined by very-low-density lipoprotein = total cholesterol − high-density lipoprotein − low-density lipoprotein.

The subfraction 3 of high-density lipoprotein cholesterol was measured by precipitating the subfraction 2 from total high-density lipoprotein with dextran sulfate as described Gidez et al.[10] Subtracting subfraction 3 of high-density lipoprotein from total high-density lipoprotein resulted in the determination of subfraction 2 of high-density lipoprotein. All of the lipoprotein assays were performed at one central laboratory (The Upjohn Co.).

The results were tabulated and compared across treatment regimens by an analysis of variance technique, paired t test, and Fisher's exact test, with significance regarded at the 0.05 level.

Results

A total of 92 patients were recruited into the study. Forty-six patients were in group I, which received continuous administration of 0.625 mg of conjugated equine estrogens with 2.5 mg of medroxyprogesterone acetate, and 46 were in group II, which received the same estrogen dosage with 5 mg of medroxyprogesterone acetate for a total of 52 weeks. Thirty-one of the patients in group I and 40 of the patients in group II completed the year-long study.

The mean age of the total study group was 55.4 years, mean gravidity 3.5, and mean height 64.3 inches, with no differences noted between the groups. The mean initial weight was 150.2 pounds and the final mean weight was 151.4 pounds, with no statistical differences noted within either treatment group. Systolic blood pressure increased significantly in the total group from

Table I. Lipid levels

	Initial (mg/dl)	*Final*
Total cholesterol		
Group I	248.30 ± 46.32	240.60 ± 38.69
Group II	243.42 ± 40.36	237.26 ± 38.14
Combined population	245.57 ± 42.09	238.74 ± 37.54
High-density lipoprotein cholesterol		
Group I	54.80 ± 18.28	58.83 ± 15.66

Data are means ± SD. Group I = 0.625 mg of conjugated equine estrogens plus 2.5 mg medroxyprogesterone acetate. Group II = 0.625 mg of conjugated equine estrogens plus 5.0 mg medroxyprogesterone acetate.

*$p < 0.05$.

123.5 mm Hg initially to 126.9 mm Hg at the end of the study ($p < 0.05$). Diastolic blood pressure decreased from an initial value of 76.6 to 74.3 mm Hg ($p < 0.05$). No differences were noted between the two treatment groups. Serum levels of follicle-stimulating hormone and estradiol were in the postmenopausal range.

Baseline lipid profile evaluations were similar in both treatment groups. Total serum cholesterol levels decreased 2.8% (6.8 mg/dl), although this was not statistically significant, and there were no differences between the two groups. High-density lipoprotein cholesterol levels showed a 4.5% (2.5 mg/dl) increase from the initial value to the one obtained after 52 weeks of the study ($p = 0.02$). No differences were noted between the treatment regimens. Low-density lipoprotein cholesterol levels decreased 7.6% (12.8 mg/dl) during the length of the study ($p = 0.04$), with no differences noted between the treatment regimens. The change in the low-density lipoprotein cholesterol level occurred at the end of the third month and they stayed stabile. Very low–density lipoprotein cholesterol levels increased 5.2% (1.2 mg/dl), although this change was not statistically significant in either treatment group or the total population. Subfraction 2 of the high-density lipoprotein cholesterol level increased by 6.3% (2.6 mg/dl) in the entire group, but this was not statistically significant and there were no differences noted between the groups. Subfraction 3 of high-density lipoprotein cholesterol levels demonstrated a statistically significant decrease of 5.1% (3.0 mg/dl) during the course of the study ($p = 0.04$), with no differences noted between the groups. The changes noted occurred at the end of the third month. Serum triglyceride levels increased 7.1% (8.0 mg/dl) during the study, but this was not significant and there were no differences between the groups (Table I).

Statistical analysis of the lipid data was performed with the baseline and 12-month values. Variations were noted in the trends of lipoprotein profiles that were obtained every 3 months. Cholesterol levels demonstrated a major decrease at 3 months, rose at 6 months, and then decreased until the end of the study. High-density lipoprotein cholesterol levels rose at 3 and 6 months and then remained unchanged. Subfraction 2 of high-density lipoprotein cholesterol levels rose until 9 months with no further change, whereas subfraction 3 decreased until 6 months and then did not change. Low-density lipoprotein cholesterol levels decreased at 3 months with a slight trend downward for the rest of the study. Very low–density lipoprotein cholesterol and triglyceride levels had the maximum increase at 6 months and then decreased slightly until the end of the study.

The bleeding data were evaluated in two ways. The first way was to divide the 52 weeks into four 13-week quarters and the second was to divide the 52 weeks into 13 4-week blocks. Any vaginal spotting or bleeding during a 24-hour day was considered an episode of bleeding. There were an average of 9 episodes of bleeding per patient in the first quarter compared with 4.5 in the second quarter ($p < 0.0005$). This diminished to 1.7 episodes in the third quarter ($p < 0.5$ comparing second and third quarters) and 1.3 in the fourth quarter, which was not a significant change from the third to the fourth quarter. Comparing the bleeding data with 4-week blocks, significant changes ($p < 0.05$) were noted in the second to third block, fourth to fifth block, and seventh to eighth block. The remainder of the changes were not significant. No differences were noted comparing the two treatment regimens.

Of the patients enrolled in the study, 35% had no bleeding during the 52 weeks. During the first 13 weeks, 43% did not bleed. This increased to 61% during weeks 14 to 26, 73% in weeks 27 to 39, and 82% in weeks 40 to 52. The distribution of the absence of bleeding was the same in both treatment groups.

Urinalysis, mammograms, liver function, creatinine, and fasting serum glucose test results demonstrated no significant changes during the study.

Endometrial biopsy specimens at the initial visit showed either atrophic or minimal tissue that was insufficient for diagnosis in the 92 patients. Twenty-one patients did not complete the study, leaving 71 patients, one of whom refused biopsy at study termination and one who underwent a total abdominal hysterectomy and bilateral salpingo-oophorectomy for an ovarian mass. Of the 69 endometrial biopsies performed at the conclusion of the study, 67 showed atrophy or had minimal tissue that was insufficient for diagnosis. Two patients demonstrated proliferative endometrium, both being in the group receiving 2.5 mg of medroxyprogesterone acetate.

Improvement was noted during the study in all the patients who had vasomotor symptoms at the time of the initial evaluation.

Twenty-one patients dropped out of the study at various intervals. Fourteen were in the group receiving 2.5 mg of medroxyprogesterone acetate and seven were in the group receiving 5 mg. Seven patients moved and were lost to follow-up. Two patients had unexplained rashes, one was too busy to keep her clinic appointments, one had multiple nonspecific somatic complaints, one had bloating and cramps, and one had unexplained abdominal pain at week 31 of the study. Eight patients discontinued the study because of vaginal bleeding. Six were in the 2.5 mg group and stopped at 4, 6, 12, 18, 18½, and 19 weeks of the study. Two patients were in the 5 mg group and stopped at 9 and 16 weeks of the study. There were no statistical differences between the two treatment groups in patients who dropped out because of bleeding.

Comment

The average American woman will live one third of her life after the onset of the climacteric, and it is becoming accepted that exogenous sex hormone therapy is appropriate for many of these patients. A 1986 bulletin from the Food and Drug Administration states that "short-acting estrogens are indicated in postmenopausal women with evidence of loss or deficiency of bone mass, to retard further bone loss, and estrogen deficiency–induced osteoporosis."[11]

There are certain well-accepted facts regarding estrogen therapy. Its use protects against osteoporosis,[12] unopposed use increases the risk of endometrial cancer,[13] the risk of cardiovascular disease is decreased with estrogen use,[14, 15] and vasomotor symptoms are adequately prevented by taking estrogen.[5] Also, the addition of a progestin for 10 to 14 days of each estrogen cycle reduces the risk of endometrial cancer to baseline or lower.[16]

The 0.625 mg dose of conjugated equine estrogen has been selected because it is adequate to obtain the beneficial effects of estrogen therapy in most postmenopausal women. The dose of 2.5 or 5.0 mg of medroxyprogesterone acetate was chosen with the rationale of protecting the endometrium while utilizing a dosage that will have minimal or no effect on serum lipoprotein levels.

Current areas of concern that we desire to address are the proper regimen of estrogen-progestin to protect the endometrium from neoplasia, minimize vaginal bleeding, treat vasomotor symptoms, and favorably affect the lipid profile. Several recent publications have suggested that a continuous combined low-dose regimen of estrogen-progestin eliminates the majority of vaginal bleeding and has either a beneficial or neutral effect on lipid profiles.[6, 17] This is in contrast to evidence that the use of 10 mg of medroxyprogesterone acetate for 10 days of each cycle has a negative effect on the high-density lipoprotein cholesterol level and its subfraction 2.[18]

It is important to appreciate that cardiovascular disease is a major cause of death in postmenopausal women.[4] Small changes in lipoprotein profiles may have major effects on rates of coronary heart disease. The Lipid Research Clinics Trial demonstrated that a 1% reduction in cholesterol level equaled a 2% reduction in coronary heart disease, and an 11% decrease in low-density lipoprotein cholesterol levels resulted in a 19% decrease in coronary heart disease.[19] A 1 mg/dl increase in high-density lipoprotein cholesterol levels may be associated with a 3% to 5% decrease in coronary heart disease.[20] The protection to the cardiovascular system by high-density lipoprotein cholesterol has been primarily attributed to its subfraction 2.[21] Ottosson et al.[18] demonstrated in a group of women treated with 2 mg of estradiol valerate a 9.2% increase in high-density lipoprotein cholesterol levels and a 16% increase in subfraction 2.[18] By the end of the third cycle, 10 mg of medroxyprogesterone acetate given for 10 days had basically eliminated these beneficial increases in serum lipoprotein levels.[18] The current study demonstrated a 2.8% or 6.8 mg/dl decrease in total cholesterol levels, a 4.5% or 2.5 mg/dl increase in high-density lipoprotein cholesterol levels, a 6.3% or 2.6 mg/dl increase in subfraction 2 of high-density lipoprotein cholesterol levels, a 7.6% or 12.3 mg/dl decrease in low-density lipoprotein cholesterol levels, a 5.2% or 1.2 mg/dl increase in very low–density lipoprotein cholesterol levels, and a 7.1% or 8.0 mg/dl increase in serum triglyceride levels. All of these changes are beneficial for protection from coronary heart disease and support the concept that low-dose continuous medroxyprogesterone acetate does not negate the beneficial effects of estrogen therapy on lipoprotein profiles.

Compliance is a serious problem with hormone-replacement therapy in the menopausal patient. Evi-

dence suggests that only 30% of patients are compliant with therapy, with fear of cancer being the major reason for discontinuing therapy.[22] Vaginal bleeding is a major symptom that distresses many patients receiving hormone-replacement therapy. Two recent studies demonstrated that only 50% of patients receiving continuous combined low-dose estrogen-progestin therapy had bleeding, with most episodes being spotting, and that it diminished with time.[6, 23] This is most likely the result of atrophic endometrium developing in the majority of patients receiving continuous combined therapy.[24]

Seventy-seven percent of the patients completed the 52-week study. Eliminating the patients who dropped out of the study for causes other than bleeding, the compliance rate increased to 90%, far above that expected for a sequential hormonal regimen.

The current data demonstrate a marked decrease in episodes of vaginal bleeding from an average of 9.1 episodes in the first 13-week block to an average of 1.7 episodes in the third 13-week block. Also, all patients had atrophic endometrium except for two taking 2.5 mg of medroxyprogesterone acetate who had proliferative changes. This regimen offers a substantial decrease in bleeding episodes and marked protection to the endometrium from development of a neoplastic process.

Debate exists as to the need for a baseline endometrial biopsy before starting hormone-replacement therapy. We do believe it is beneficial to obtain the endometrial biopsy specimen to rule out asymptomatic disease but appreciate that evidence exists that administration of progesterone to symptom-free postmenopausal women revealed those who did not have any vaginal bleeding to have had nonpathologic endometrial histologic findings.[25] It remains to the clinician to decide which method to use for baseline endometrial evaluation. Because most endometria remain atrophic with continuous combined low-dose estrogen-progestin regimens, it suggests that the clinician need only repeat the biopsy in those patients who have a marked change in vaginal bleeding while receiving the therapy.

The subtle differences noted between the two dosages of medroxyprogesterone acetate (2.5 and 5.0 mg) do not allow us to significantly distinguish one as being better than the other. Our suggestion is to start with the 2.5 mg dose along with a 0.625 mg dose of conjugated equine estrogen and, if spotting is heavy or persistent with normal endometrial histologic results, to increase to the 5 mg dose. This is an empiric suggestion and needs scientific substantiation.

It is our opinion that the use of a sequential regimen of estrogen-progestin does not increase the risk of breast cancer. The impact of a continuous low-dose regimen of estrogen-progestin on the incidence of breast cancer is unknown, but we believe that it is unlikely to be increased.

It is our belief that we have demonstrated the marked benefits of a continuous combined low-dose estrogen-progestin regimen for the menopausal patient. Menopausal symptoms are diminished, lipoprotein profiles are beneficially altered to protect the cardiovascular system, vaginal bleeding is diminished, and the endometrium is protected from neoplasia. As clinical evidence for the advantages of this approach accumulates, it is a possibility that this regimen will be the primary one for hormone-replacement therapy in the menopausal patient.

Discussion

DR. ROBERT W. REBAR, Cincinnati, Ohio. No less an authority than the esteemed epidemiologist Dr. Elizabeth Barrett-Connor has stated that, "For the average North American woman, who will be postmenopausal for one third of her life, the benefits of estrogen seem strongly established."[1] However, both the risks and side effects of estrogen-replacement therapy in postmenopausal women have caused clinicians to investigate new and different ways of administering estrogens. Moreover, as the First International Consensus Conference on Progestogen Use in Postmenopausal Women concluded, "Basic science, clinical, and epidemiological studies have shown that progestogen treatment is efficacious and is indicated for opposing the effects of oestrogen on the endometrium."[2] Such considerations have led a number of investigators and pharmaceutical houses to suggest the use of continuous low-dose estrogen-progestin therapy for postmenopausal women.

This article summarizes a pharmaceutical company–sponsored study aimed at documenting the efficacy of combined estrogen-progestin therapy. It is presumed that such therapy will reduce the incidence of uterine bleeding and the risk of endometrial hyperplasia while not adversely affecting the beneficial effects of estrogen on the ratio of high-density to low-density lipoprotein cholesterol. Moreover, no such study has attempted to evaluate what should be the optimal ratio of estrogen to progestin in such therapy. The selection of the dosages of each steroid is empiric, being based on data collected from patients receiving sequential therapy.

Unfortunately, the design of the present study, as well as of most such clinical trials, does not directly prove or disprove such assumptions. In the present study no control patients were included who took no estrogen (placebo), estrogen alone, or sequential estrogen and progestin for the entire year. Thus it is impossible to determine if combined estrogen-progestin therapy is more efficacious than any of these other modes of therapy. It should be noted that the same consensus conference on progestogen use concluded that it is ethical to include a study group of women who have not undergone hysterectomy who are receiving unopposed estrogen in carefully monitored clinical trials.[2] However, no consensus was reached on the inclusion of a placebo group receiving no hormonal therapy.

Thus your conclusion that your data ". . . support the concept that low-dose continuous medroxyprogesterone acetate does not negate the beneficial effects of estrogen therapy on lipoprotein profiles" is inappropriate. True, you did demonstrate an increase in high-density lipoprotein cholesterol and a decrease in low-density lipoprotein cholesterol levels. However, this study does not prove that the beneficial effects are not less than those of estrogen alone or estrogen administered sequentially with a progestin. Given than, as you noted, even "small changes in lipoprotein profiles may have major effects on rates of coronary heart disease,"[8] the omission of these control subjects is of major significance.

You state that you could not distinguish any significant differences between the 2.5 and 5.0 mg doses of medroxyprogesterone. In view of evidence that the progestogenic effects on lipoprotein cholesterol levels are dose dependent,[3] it would seem prudent, as you suggest, to use the lowest dose of progestin that prevents endometrial hyperplasia.

In addition, it is possible that any reduction in the incidence of coronary heart disease in women taking estrogen is in part the result of some other or as yet unidentified property of exogenous estrogens. For example, estrogens appear to cause vasodilatation by stimulating prostacyclin production.[4,5] Progestins appear to have the opposite effect, abolishing this stimulation of prostacyclin production. It is also possible that this property is antagonized by progestin. Only longer-term studies comparing sequential and continuous estrogen-progestin therapies will determine if there is any difference between the therapies.

Also not considered in the current study are the effects of progestins quite apart from antagonizing the effects of estrogens. Progestins have significant effects on liver enzymes. The long-term consequences of any progestin-induced changes remain to be identified.

As presented, the bleeding data are unclear. You tell us that any vaginal spotting was considered 1 day of bleeding. You than go on to discuss the number of "episodes of bleeding." It is not clear if an "episode" is equivalent to 1 day or to an interval of continuous bleeding for 1 or more days. Also of note is your observation that the bleeding was not significantly diminished in the fourth quarter compared with the third

quarter of this year-long study. Moreover, no data are provided as to how many of the women did and how many did not continue to bleed during the study. The patterns of bleeding observed are not discussed as well.

In this regard, the failure of 21 patients to continue estrogen-progestin therapy during the course of this study is particularly disconcerting. Apparently only 8 of the 92 patients discontinued this study because of vaginal bleeding. However, there can be no doubt that these women were particularly motivated: they had elected to participate in a research study and were probably compensated reasonably well for completing the study successfully. What percentage of treated women who are not part of a study and who are receiving continuous estrogen-progestin therapy will discontinue the medications if there is any irregular and unexpected bleeding?

Although the investigators tell us that all the patients who had vasomotor symptoms at the time of initial evaluation were improved with therapy, no data are presented. Because it is possible to quantitate hot flushes objectively and subjectively, such data should be available. Similarly, the effect of the estrogen-progestin therapy on calcium excretion and bone density over time are also needed to evaluate this therapy completely. In addition, the depressive effects of progestogens are well known. The investigators should provide us with data that daily combined therapy did not have a negative impact on the psychologic states of the women.

Strangely absent from the discussion is any consideration of the effects of combined estrogen-progestin therapy on the incidence of breast cancer. Clearly the present study cannot answer this important question. Opinions are divided on this issue. The observation that maximal mitotic activity in breast tissue occurs on about day 25 of the normal menstrual cycle at the time of maximal progesterone secretion by the corpus luteum suggests differences in cellular activity compared to the endometrium.[6] Maximal mitotic activity in the endometrium occurs in the follicular phase of the cycle, with glandular tissue being shed monthly. Henderson et al.[7] have suggested that progestins cannot be presumed to have an antiestrogen anticancer effect on the breast, and others have reached this same conclusion more recently.[8] Longer and larger trials will be required to determine if exogenous estrogen alters the risk of breast cancer in postmenopausal women and to determine how the addition of a progestin modifies the response to estrogen.

In summary, your study presents important data about the possible role of continuous combined low-dose estrogen-progestin therapy for postmenopausal women. However, the study has significant weaknesses, as must be true of any study involving a small number of patients followed up for only 1 year. Data from larger and longer studies are required before definitive conclusions can be drawn about the relative efficacy of combined therapy. Until such data are available, it is my opinion that it is unwise to recommend anything except sequential therapy to postmenopausal women who have a uterus. Moreover, because of the potentially harmful effects of progestins, it seems prudent to administer estrogens alone to postmenopausal women who have undergone hysterectomy. To some, these may be regarded as controversial recommendations. I would suggest, however, that these are prudent and cautious suggestions and would note in closing the comments of the First Consensus Conference on Progestogen Use in Postmenopausal Women: "There are insufficient long-term histological and epidemiological data to advocate the routine use of daily doses of both progestogen and oestrogen (continuous-combined therapy). The long-term metabolic consequences of daily progestogen addition need to be determined."[2] For the sake of impartiality, I must note that this conference also went on to conclude, "However, continuous-combined therapy may be an option."[2]

DR. RONALD T. BURKMAN, Detroit, Michigan. Devising an appropriate regimen for hormone replacement therapy during menopause is a subject of considerable topical interest, given the estimated 40 million women in the United States who are potential candidates for this therapy. However, for a variety of reasons it has been estimated that only 10% of the potential candidates for hormone replacement actually take the medication.[1] On the benefit side of the ledger is relief of vasomotor symptoms, reduction of bone mineral loss, and probable reduction in coronary heart disease, whereas on the risk side one includes neoplasia (endometrial and possibly breast) and perhaps gallbladder disease. You have evaluated two continuous combination approaches and have examined resultant endometrial histologic findings during a 1-year trial period.

In regard to the lipid-lipoprotein changes, both regimens appeared to demonstrate favorable effects, with mean changes from baseline varying between 1% and 10%. However, when one examines the standard deviations, there seems to be considerable variability. Be-

cause data were collected at two institutions, it would be important for you to provide us with information as to what was done to ensure that the results between the two institutions were comparable. Although the two treatment groups did not show statistically significant differences relative to lipids and lipoproteins, there were trends, albeit inconsistent ones, that suggest that the regimens might differ in important ways. For example, the group taking 2.5 mg of medroxyprogesterone acetate showed a 7.4% increase from baseline for high-density lipoprotein cholesterol levels, whereas the group taking 5 mg showed only a 2.2% increase, a difference that may be of some clinical significance. Clearly the final sample sizes of 31 and 40 subjects are too small to evaluate this issue adequately. As an aside, it should be noted that all investigators use lipid-lipoprotein changes as a proxy for coronary heart disease because the measurement of outcome variables such as myocardial infarction would require prohibitively large sample sizes for clinical trials, as well as create other design problems. Although the relationship of lipid-lipoprotein changes to incidence of coronary heart disease has been well established in several studies, it is important to recognize that recent animal studies suggest that sex steroids may also act outside the lipid-lipoprotein system to such an extent that lipoprotein changes could become less predictive of later risk of coronary heart disease.[2]

In regard to vaginal bleeding, it appears that the frequency of bleeding declined over time; significant differences between the treatment groups were not presented. However, the study dropout rates suggest that the lowest-dose progestin regimen was less acceptable because 13% of women in this group compared with 4% in the higher-dose group discontinued the study because of bleeding.

The endometrial histologic data also suggest that the lower-dose progestin regimen may be less effective than the higher-dose regimen in maintaining atrophic conditions. Of the women who completed the study, two or 6.5% of the women in the group taking 2.5 mg of medroxyprogesterone acetate showed conversion from an atrophic to a proliferative endometrium. Whether this dose would place women at undue risk for endometrial cancer is unknown. An obvious question is, how does one monitor patients on a continuous combination regimen particularly if there is inconsistency in the bleeding patterns? Although Padwick et al.[3] have suggested a useful approach for women receiving sequential hormone-replacement therapy, it is not an approach that can be used with continuous combination therapy. Scientifically, this concern may become less of an issue if the cardiovascular-protective actions of estrogen replacement continue to be borne out. As suggested in the "risk model" of Ross et al.,[4] far more women would be saved from cardiovascular deaths than would be lost from endometrial cancer, even if we elected not to prescribe a progestin with the estrogen. However, whether consumers would accept fewer heart attacks for more cancer is unclear. In any event, the task that faces us is to make these medications not only efficacious and safe but also far more acceptable, particularly from the standpoint of side effects. More clinical trials are needed to allow us to define approaches better that fit our patients' needs.

Dr. Eduard Eichner, Cleveland, Ohio. Having been with research for years, the sequential treatment, as far as I am concerned, is out in therapy because it produces bleeding in almost 100% of women; therefore they drop out of the study. I am not talking about the efficacy in "saving things" but in getting patients to do a study.

Dr. Russell Malinak, Houston, Texas. Did you correlate the time of onset of the menopause with abnormal bleeding on your regimens? It has been a clinical observation that women in the early postmenopausal period will tend to have more abnormal bleeding than have women in the late postmenopausal period.

Dr. Weinstein (Closing). To answer some of the questions that were addressed, first the concept of menopause that I accept is that it is a hormone-deficient state. If one accepts that and makes an analogy to hypothyroidism, I do not think you can have a control group in a current study. I personally would not do a study that has a control group of patients without any hormonal therapy.

The other thing would be to use estrogen-only therapy in the patient with an intact uterus. I think you can do that, but I do not know who is going to accept the risk if an atypical endometrial hyperplasia develops, regarding the cost of the curettage and the potential for surgery and related hysterectomy. I think it is a difficult issue.

There are superb data regarding unopposed use of estrogen as related to the development of endometrial carcinoma. I personally have difficulty with it, although I admit that unopposed estrogen in the majority of patients is a very good therapy; unfortunately, in the society we live in I am not sure we can do that any more.

If one looks at our lipid data, the reasons that we did not have control groups are as I stated. However, if you compare our lipid data with those of the Lipid Clinic Research Study that was published in *The New England Journal of Medicine* of patients treated with estrogen only with measured lipid profiles, our lipid data are similar. There is no major difference. If one will accept this historic control, I believe it shows that

lipid data of the low-dose continuous regimen are not affected by the medroxyprogesterone acetate.

A major reason for a study like this is to improve compliance. Use of sequential hormonal therapy is very nice. You give it to the patients, they go home, and you do not see them again. Also, they do not get repeat prescriptions. There are some excellent data from the Boston group that show that the average compliance for sequential hormonal therapy is 30% to 40%. If we truly have a hormone-deficient state and we really want to help the health care of aging women, I think we have to have a regimen with a better compliance record.

Dr. Burkman commented about the samples. All the samples were run by one central research laboratory. They were collected at the two institutions, but they were all run in one place, so the variation should be the same. The 2.5 mg regimen did have a better lipoprotein profile with increased high-density lipoprotein levels, and that is why we suggest that one start with a 2.5 mg regimen. The patients who have continuous nuisance spotting that goes on for more than 20 weeks are the patients we think will benefit from the 5 mg dosage. In general in our clinic population we start at the lower dosage.

How do you monitor the patients? Well, the question is always asked, do you do yearly endometrial biopsies? If you have a baseline endometrial biopsy result, you know where you are going, and you know from where you started. If you do not have an endometrial biopsy as a baseline, and the patient has bleeding, I do not think you have any idea where you are because you really do not know where you started.

So we do the baseline biopsy study, and then we repeat it if the patient has any unusual change in bleeding patterns. In the last 3 years in the two combined studies we have done, it has been necessary to repeat one endometrial biopsy that demonstrated atrophic changes. At this time we do not advocate yearly or repeat endometrial biopsies.

The question by Dr. Malinak regarding the time of onset of menopause, our patients averaged 55 years of age. They were at least 1 year menopausal. We had no patient in the study over 60 years and none under 46 or 47 years, as I recall. So our patients tended to be on the young side of menopause, and his point is well taken that younger women, both menopausal and perimenopausal, tend to have the most bleeding problems.

Ultrasonography and external cephalic version at term

William L. Donald, MD, and John J. Barton, MD

Chicago, Illinois

Sixty-five patients with nonvertex presentations at term were evaluated by ultrasonography to determine which factors were associated with a successful external cephalic version. Amniotic fluid volume, placental localization, type of breech, position of the fetal spine, and whether the breech had descended were determined and analyzed by χ^2 analysis. Only a frank breech and an anteriorly located fetal spine were associated with a successful version. Four episodes of fetal bradycardia occurred, none requiring operative intervention. There were no episodes of maternal bleeding or dislodgement of the placenta. Fifty-eight percent of all breech presentations were converted and 62% were delivered vaginally. We conclude that ultrasonography is useful in the evaluation of patients with a nonvertex presentation at term and can be used to predict which patients are likely to undergo a successful external cephalic version. (Am J Obstet Gynecol 1990;162:1542-7.)

Key words: Ultrasonography, external version

The cesarean section rate has risen progressively from 4.0% in 1970 to 24.6% in 1986.[1] In 1970, 14.0% of infants in breech positions were managed by cesarean delivery; in 1986 that number was up to 86%, and in some centers 100% of breech presentations are managed by cesarean delivery.[1] Fig. 1 shows the recent trend of breech deliveries at Illinois Masonic Medical Center.

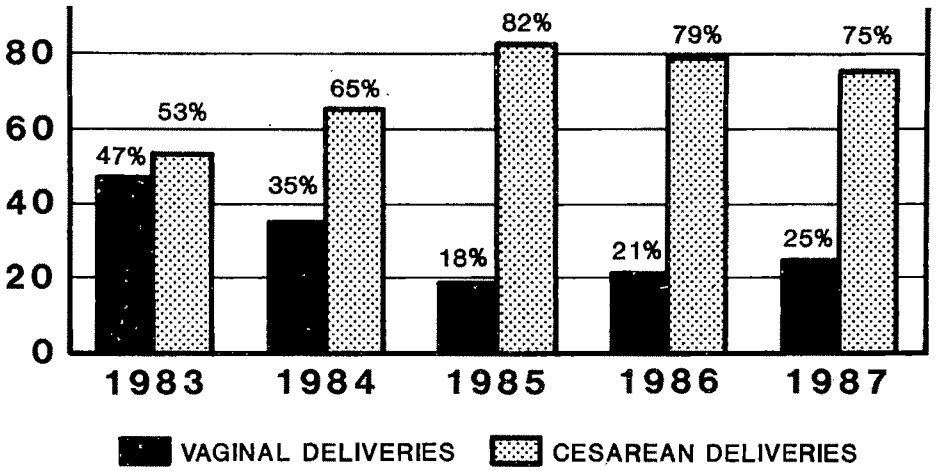

Fig. 1. Management of breech presentation at Illinois Masonic Medical Center.

External cephalic version has been shown to be successful in managing the nonvertex presentation at term.[2-4] Ultrasonography has assumed an important role in the assessment of these patients. The purpose of this study was to assess which factors detected on ultrasonographic evaluation of nonvertex presentations at term are associated with a successful external cephalic version under tocolysis.

Patients and methods

From July 1986 through October 1988 all patients with a nonvertex presentation at term referred from private obstetricians, the nurse midwifery service, and the obstetric clinic of Illinois Masonic Medical Center were included in the study. Exclusion criteria are listed in Table I. No patients referred were in labor. All patients who met inclusion criteria were asked to participate. All patients underwent nonstress testing before the start of the procedure, an intravenous line was begun on all patients, and all patients signed an informed consent for external cephalic version and emergency cesarean delivery. An ultrasonographic evaluation was then performed on all patients. The parameters evaluated were amniotic fluid volume, fetal lie, and presentation. If breech, the type of breech was determined by assessment of the relationship of the lower limbs to the fetal abdomen. The descent of the breech into the pelvis was assessed and in several cases confirmed by vaginal examination. The position of the fetal back was determined: anterior or posterior. The location of the placenta was determined: predominantly anterior or posterior. Rather than using amniotic fluid index as described by other investigators, our criterion for decreased amniotic fluid was defined as a vertical pocket of fluid less than 2 cm in depth. All data on each patient were entered onto a fact sheet and later analyzed. A

Antepartum hemorrhage
Previous uterine scar
Multiple pregnancy
Uncontrolled hypertension
Rupture of membranes
Less than 37 completed weeks
Evidence of placental insufficiency or fetal distress
Morbid maternal obesity

prophylactic tocolytic was initiated in all cases. There are many studies in the literature that do not use a tocolytic as part of the version attempt. We thought that a tocolytic was needed and is our preference in performing versions. The tocolytic used was ritodrine (Du Pont Pharmaceuticals, Wilmington, Del.). It was begun 30 minutes before the version attempt. The external cephalic version method as described by Ranney[5] was used. All versions were done by the same physicians. Patients were monitored for 1 hour after each version, regardless of whether the attempt was successful. A maximum of two attempts at one sitting was made on each patient.

Data were analyzed by the χ^2 method with Yates' correction and the Fisher exact test.

Results

Sixty-five patients were enrolled in the study. Thirty-eight (58%) of the patients underwent a successful version. Forty-one (63%) of the patients studied were delivered vaginally, including those with successful conversions, four persistent breech presentations, and three spontaneous cephalic versions. The spontaneous cephalic conversion rate of 4.6% is similar to results that have been reported by other investigators.[6, 7] Of

the 27 unsuccessful attempts, 20 of the patients underwent cesarean delivery. There were four vaginal deliveries of frank breech presentations; we used criteria developed at our institution for breech delivery. These criteria are listed in Table II. Table III shows the external cephalic version results, and Table IV shows the results of statistical analysis of the data. The greatest success was obtained with a frank breech presentation and when the fetal spine was in an anterior position. This is somewhat contrary to the current theory that the amniotic fluid volume is the most important criterion for a successful version. Obviously, in cases in which oligohydramnios, as defined by our criteria, was present, a vigorous attempt to convert the fetus was not used. Further fetal evaluation was done to determine any causative pathologic factors for the oligohydramnios. There were four episodes of fetal bradycardia in the 65 patients. There were no fetal or maternal deaths in the study group. Twelve patients in the study presented with a transverse lie. These patients were excluded from the totals in Table III. They constitute a separate study group.

Comment

External cephalic version has been shown to be effective in the management of the breech presentation at term and in reducing the cesarean section rate in breech presentations at term.[7-9] Ultrasonography has assumed an important role in the management of these patients. We used ultrasonography to evaluate all patients undergoing an external cephalic version at term. The objective was to determine which factors were associated with a successful version. We found only two: the type of breech and the position of the fetal spine. Unlike Ranney,[5] who found decreased amniotic fluid volume to be responsible for 14.8% of his failed versions, we did not find this association. We did not aggressively attempt version in these cases and submitted these patients to further testing to determine if there were any associated pathologic processes causing the oligohydramnios. Neely,[10] who used an anesthetic during his versions, found 17.8% of his failures to be the result of a decreased amniotic fluid volume. Decreased amniotic fluid volume has been considered to be a relative contraindication to an external cephalic version.

Fianu and Vaclaviahova[11] had a 96% success rate when the placenta was implanted on the anterior or posterior uterine wall and only a 44.4% success rate when the placenta was cornual or fundal. Placental location, with the obvious exception of placenta previa, was not found to be of significance in our study. Initially, cornual and fundal placental locations were evaluated, but then we assigned them to either anterior or posterior groupings depending on where the major

part of the placenta was located. An anterior placenta has been considered to be a relative contraindication to an external cephalic version by some authors.[3] Our data do not support either increased or diminished success.

Extension of the fetal legs and, as such, the type of breech presentation have been believed not to play a role if tocolysis is used.[12] We found in our study that a nonfrank breech was associated with a relative failure rate of the external cephalic version. Even under tocolysis, with an incomplete breech the fetal leg might serve as a splint, decreasing the ability to turn the fetus.

The posterior position of the fetal spine was associated with an increased rate of failure of external cephalic version in our study group. With the fetal back located posteriorly, only the soft parts of the fetus are palpable. They are more difficult to use as points of leverage in turning the fetus. The posterior position of the spine may also make the umbilical cord more vulnerable to compression during the version attempt. The four episodes of bradycardia in our study were associated with the back in a posterior position and were probably caused in this manner.

When the fetus in the breech position has descended into the pelvis, the success rate of the external cephalic version has been found to be decreased by some investigators. Strictly speaking, this is not an ultrasonographic factor; however, by placing the linear transducer at the level of the maternal symphysis pubis and repeatedly angling up and down, one is able to assess whether the presenting part has entered the pelvis or still lies above the pelvic brim. In our study we did not find this to be a factor. However, all of our patients were placed in a lateral tilt and Trendelenburg position before the start of the external cephalic version to prevent possible maternal supine hypotension. Such preparation may account for the reason that this was not found to be a factor in our study.

Without external cephalic version, about 3% to 4% of all term deliveries would be in breech presentation.[13, 14] Vaginal delivery of the unselected breech infant at term is associated with an increase in perinatal mortality rates. Compared with the vertex presentation at term, there is a threefold increase in the mortality rate and a twelvefold increase in the morbidity rate in unselected cases.[15] Our criteria for vaginal delivery of an infant in the breech position are listed in Table II, and our results for the years 1983 through 1987 are shown in Table V. The trend in contemporary obstetric practice has clearly been toward cesarean delivery for the breech presentation. External cephalic version provides an attractive alternative to this longstanding and controversial obstetric dilemma. In this study we found a frank breech presentation and the fetal back in an anterior position to be the factors on ultrasonographic evaluation associated with a successful external cephalic version. We did not find that amniotic fluid volume, placental location, or station of the presenting part to be of significance in the success of the version. We conclude that ultrasonography with tocolysis is useful in the evaluation of all patients with a nonvertex presentation at term undergoing an external cephalic version. All patients should be offered this procedure, and in the hands of an experienced obstetrician it may reduce the morbidity and mortality rates associated with vaginal breech delivery, including cesarean delivery of the infant breech at term.[16]

Discussion

DR. SAM T. SCALING, Casper, Wyoming. This is an interesting study attempting to delineate further the

factors associated with successful external cephalic version in patients at term. The overall success rates are comparable to those of other studies of external cephalic version at term.

Although the factors in this study associated with successful version at term, that is, frank breech presentation and anteriorly located fetal spine, may help predict which patients will have a successful version, the clinical absence of these factors should not deter a clinician from attempting external cephalic version in most or all patients with nonvertex presentations who otherwise have no contraindications to the procedure.

Second, it would be good to know if any of the factors studied would be associated with increased morbidity or complications such as bradycardia, isoimmunization, or even significant patient discomfort. Indeed this was determined with one factor, the posterior position of the fetal spine and the apparent relationship to the occurrence of bradycardia. Because the essence of a successful version also includes safety to both the mother and fetus, it becomes imperative that factors that increase morbidity or mortality rates be known.

The cases of transverse lie are included in the statistical analysis of the data, but the successful factors found (frank breech and position of the fetal spine) do not seem to apply in analyzing these cases. By removing the cases of transverse lie from your Table II, the overall success rates for version in breech presentations remain the same. In analyzing the data and factors that apply to version in breech presentation, it seems more prudent to consider transverse lie as an entirely separate study and analyze accordingly.

I have two questions relating to antepartum hemorrhage as an exclusion factor in your study. First, how did you define antepartum hemorrhage in your study? Second, since up to 20% of obstetric patients will have antepartum hemorrhage and only about 50% of those who bleed have a resultant pregnancy loss, by ruling out placenta previa with ultrasonography should not some of this subset of patients be afforded the opportunity for external cephalic version?

Dr. Peter K. Thompson, Houston, Texas. This study helps us move, ever so slowly, toward better understanding and hopefully acceptance of external cephalic version. An objective was to find if ultrasonography could predict the probability of success in external cephalic version. It is interesting to know that of the eight factors studied only two had any association. Your results suggest that we should be more optimistic about external cephalic version if the breech position is frank and the fetal spine is anterior. Conversely, should the lack of these two factors preclude an attempt at external cephalic version?

A similar article by Fergerson et al.[1] in 1987 studied maternal and fetal factors before external cephalic version in 172 patients. In their study, factors associated with success were (1) noncornual placental location, (2) normal or increased amniotic fluid, (3) nonfrank presentation, and (4) fetal spine in the lateral position. In 1988 Fortunato et al.[2] reported on 67 patients and they found only two significant negative factors: descent of the breech presentation and fetal spine in the posterior position. Consequently, you, Fergerson et al., and Fortunato et al. agree only that the position of the fetal spine is a significant factor in predicting success. It should be mentioned that even when the position of the fetal spine was unfavorable (posterior), the success rate with external cephalic version was at least 48% in the study by Fergerson et al. but only 13% in the study by Fortunato et al.

I have often heard the comment from detractors of external cephalic version that successful versions represent those fetuses that would probably turn spontaneously if left alone. In this study the spontaneous cephalic conversion rate was 4.6%. We know that in studies with control subjects[3, 4] the rate of spontaneous version after 36 to 37 weeks is 14% to 20%. The rate can be as high as 30% in multiparous patients.[5] In the majority of studies on external cephalic version, when attempted beyond 37 weeks the success rate is at least 45% and more often 60% to 70%. Certainly these facts do not support the attitude of leaving the breech alone in hopes of a spontaneous conversion.

I have two questions: first, why did you use only anterior and posterior localization of the placenta and delete the cornual and fundal category? As mentioned earlier, other investigators have been able to show that cornual implantation decreases the success rate. Second, what is your opinion about the need for ultrasonography in external cephalic version other than to confirm the presentation if there is doubt? I believe the information obtained by a full ultrasonographic examination seems to be of minimal prognostic value and its cost would not justify its routine use. Perhaps the place for detailed ultrasonographic findings may be to explain why a procedure failed or convince the physician not to try again.

Dr. Washington Hill, Omaha, Nebraska. In your protocol you mentioned obtaining a mediolateral film for evaluation, I assume, of hyperextension of the head. You went over that rather quickly. Could you give us some further information on that because that is something that many of us do not do.

Did you consider using an alternative tocolytic? Since you mention that some patients do not like the side effects of ritodrine, perhaps some other tocolytic such as magnesium sulfate might be helpful.

Did you consider having a Kleihauer-Betke stain done on patients who had an anterior placenta to see whether they had any fetal-maternal hemorrhage? I was somewhat surprised that you did not find the station of the breech to reduce your success rate, because many of us have found that the engaged breech is somewhat hard to turn.

Dr. Kenneth Moise, Houston, Texas. Did you use a two-operator technique or a single-operator technique?

Dr. Robert W. Rebar, Cincinnati, Ohio. What was the outcome of the infants who were treated with external version compared with those not so treated? Second, what was the difference with regard to the morbidity of the mothers in each group? Third, what was the difference with regard to costs incurred in each group? I would think that the answers to these questions would be interesting at least from the perspective of health care.

Dr. Daniel A. Rightmire, Springfield, Illinois. Were there recurring factors after version that prevented vaginal delivery? For example, cord presentation or compound presentation may follow a "successful" version and still result in cesarean delivery.

Dr Barton (Closing). The subject that Dr. Donald addressed is really just one thread in the whole cloth of the management of the breech presentation. Obviously, the attempts at external cephalic version are done to avoid facing the dilemma of whether to deliver the breech vaginally or abdominally. I present this statement to you: "In current obstetrical practice, vaginal delivery of a breech presentation is tantamount to malpractice." You will find this statement in the trial transcripts of an expert witness appearing in the Circuit Court of Cook County, Illinois, where the defendant had a bad outcome in a vaginal delivery of a fetus in breech presentation. I asked 12 of my colleagues if they had ever heard this statement made by one of their colleagues. Six different names were mentioned as physicians adhering to that standard.

At Illinois Masonic Medical Center we reviewed our statistics on the management of breech presentations and the perinatal outcomes. The questions we addressed were the following: Are we still managing breech presentations with vaginal delivery and, if managed vaginally, is this justified by outcome criteria; are we teaching our current generation of obstetricians the art and technique of vaginal breech delivery, or will we become one-operation technicians, performing only cesarean sections?

From 1983 through 1987 we had 10,476 consecutive deliveries. There were 344 breech presentations, for a rate of 3.28%. This is consistent with what we find in the textbooks for the incidence of breech deliveries. From 1983 onward, we caught on to the concept of cesarean delivery for the breech presentation, and the percent of vaginal deliveries reached a trough in 1985. Then we began to realize that our past professors such as Dr. Mengert and others were correct when they pointed out that the selected vaginal breech delivery with proper management skills was the tool in the trade and skills of obstetricians. As a result, the number of vaginal breech deliveries has begun once again to increase at some centers around the country, including ours.

In analyzing the perinatal outcome, one will find that in the unselected, unmanaged breech delivery that fell outside our criteria there was certainly poor perinatal outcome. However, in cases in which our criteria were met and the infant was 2500 gm or more the perinatal morbidity and mortality rate was 0%. Thus I believe that our data answer the questions that we posed, and, yes, obstetricians are still being taught the art of breech deliveries in Chicago.

In answer to some of the questions from the floor, only patients with antepartum hemorrhage in the third trimester were excluded from the study. We agree that the transverse lie probably constitutes a separate group of patients, and that group should be analyzed separately. However, it should be emphasized that in this group we were able to convert 57% of these patients to a cephalic presentation and achieve vaginal delivery in 67%. This group of patients should definitely be considered for external cephalic version and not routinely scheduled for cesarean delivery. Did we attempt an external cephalic version if all of our criteria were not met? Yes, we did in some cases; however, we expected, and did get, a higher failure rate in those patients. In answer to Dr. Washington Hill's question concerning the use of an alternative tocolytic, we felt comfortable with our methods and agents. In response to the question of whether we used the single- or double-operator technique, we used the single-operator technique, all performed by the same perinatologist: Dr. Donald. To answer Dr. Rebar, I think that perhaps the answers to fiscal economy are obvious. We are now delivering 25% of our breech presentations vaginally. All meet our criteria and, in my view, the most controlling factor for a favorable outcome was the steady and expected descent of the breech during the active phase of labor.

Cordocentesis for rapid karyotyping

Dinesh M. Shah, MD,[a] Periclis Roussis, MD,[a] Janet Ulm, MSSW,[b] Phillipe Jeanty, MD,[c] and Frank H. Boehm, MD[a]

Nashville, Tennessee

Pure fetal blood was obained by cordocentesis in 101 fetuses of 96 patients at 15 to 38 weeks' gestation. Rapid karyotype was obtained within 2 to 4 days by fetal lymphocyte culture. Chromosomal abnormality was detected in 12 (11.9%) fetuses. Abnormal karyotype was found in 5 of 44 fetuses with structural malformations, 3 of 13 fetuses with intrauterine growth retardation or oligohydramnios, 1 of 3 fetuses with nonimmune hydrops fetalis, 2 (one monozygotic set) of 10 discordant twins, 1 of 12 isoimmunized gestations, none of 8 cases with advanced gestational-maternal age, and none of 6 immune thrombocytopenia cases. This suggests that rapid karyotype should be obtained in all cases of fetal strutural malformations, intrauterine growth retardation, and nonimmune fetal hydrops, and may be obtained incidentally in isoimmunized pregnancies and discordant twins to assist in clinical management. (AM J OBSTET GYNECOL 1990;162:1548-53.)

Key words: Cordocentesis, rapid karyotype

Since Daffos et al.[1] first described their percutaneous umbilical blood sampling procedure for fetal blood sampling in utero, several reports[2-5] have appeared in the literature that describe its use for various indications. One important indication for percutaneous umbilical blood sampling, or cordocentesis, is rapid determination of fetal karyotype. Williamson et al.[6] reported on abnormal pregnancy sonogram as a selective indication to obtain fetal karyotype. In their report, amniocentesis and cordocentesis were used to obtain fetal karyotype.

Nicolaides et al.[7] reported on pregnancies with fetal anomalies detected by sonogram for which fetal blood samples were obtained with fetoscopy for the purpose of rapid karyotyping. Daffos et al.[8] performed cordocentesis in 39 of 562 cases for rapid karyotyping, Weiner[3] reported 33 cordocentesis procedures for rapid karyotyping, 24% of which had an abnormal karyotype. We hereby report our experience with 96 patients who underwent cordocentesis and had rapid determination of fetal karyotype.

Patients and methods

Patients who were referred to Vanderbilt University Medical Center between October 1986 and March 1989 and subsequently underwent cordocentesis are included in this report. Cordocentesis was performed under a program approved by the Committee for the Protection of Human Subjects, and all patients signed forms of informed consent for the procedure. Detailed high-resolution sonographic examination (SAL77A, Toshiba, Tustin, Calif.) was performed in all cases to confirm the diagnosis, assess the extent and severity of existing fetal anomalies, and exclude or identify other possible associated malformations. All patients underwent appropriate genetic counseling.

Fetal blood sampling was performed under local anesthesia with a 20 gauge 9 or 12 cm needle (Becton-Dickinson, Rutherford, N.J.) under full aseptic precautions and sonographic guidance by the method described by Daffos et al.[1] Sedation was occasionally induced for specific clinical indications, such as maternal anxiety or discomfort after initiation of the procedure. Tocolytic agents were not administered unless the patient was undergoing tocolytic therapy for preterm labor, or if localized uterine contraction occurred in response to needle insertion. The site of needle insertion depended on cord insertion and placental location. Fetal injection of pancuronium bromide (Pavulon, Organon Inc.) was rarely used, except in cases with posteriorly implanted placentas in which excessive fetal movement interfered with cord puncture. Fetal origin of the blood sample was determined by saline solution flush at the time of procedure, and purity was confirmed by the Kleihauer-Betke test.

Results

Mean maternal age of the study population was 27.1 years. Mean gestational age of the study population was 26.9 weeks, with a range of 15 to 38 weeks. The clinical indications for cordocentesis and the number of abnormal karyotypes found in each group are listed in

Table I. Indications and results of rapid karyotyping

Clinical indications	*Total No. of fetuses*	*No. of abnormal karyotypes*
Fetal structural malformations	44	5
IUGR or oligohydramnios	13*	3*
Nonimmune hydrops fetalis	3	1
Advanced gestational—maternal age	8	0
Discordant twins	10	2
Isoimmunization	12	1
Immune thrombocytopenic purpura	6	0
Other	5	0
TOTAL	101	12

*One fetus with IUGR also had obstructive uropathy.

Table II. Findings in cases of renal or urinary tract abnormalities

No.	*Findings*	*Gestational age (wk)*	*Karyotype*
1	Obstructive uropathy	18	Normal
2	Obstructive uropathy	20	Normal
3	Obstructive uropathy	22	Normal
4	Obstructive uropathy	16	Normal
5	Echogenic multicystic kidneys	27	Normal
6	Bilateral hydronephrosis	30	Normal
7	Renal agenesis	35	46,XY(4p−)

Table III. Findings in abdominal-gastrointestinal abnormalities

No.	*Clinical findings*	*Gestational age (wk)*	*Karyotype*
1	Omphalocele	29	47,XX+18
2	Omphalocele	20	Normal
3	Ompahlocele	38	Normal
4	Omphalocele	27	46,XY−13+der(13) t(13q18p)
5	Gastroschisis	30	Normal
6	Small-bowel obstruction	25	Normal
7	Duodenal atresia	24	Normal

Table IV. Findings in umbilical cord abnormalities

No.	*Clinical findings*	*Gestational age (wk)*	*Karyotype*
1	Single umbilical artery	33	47,XY+13
2	Single umbilical artery Umbilical cord cyst Intraabdominal cyst	24	Normal
3	Single umbilical artery	32	Normal
4	Single umbilical artery Renal anomaly Clubbed foot and hand	32	47,XY+13

Table I. The major indications for rapid karyotyping were fetal anomalies and intrauterine growth retardation (IUGR) or oligohydramnios. Incidental rapid karyotyping was done in all cases of isoimmunized pregnancies and in women with immune thrombocytopenia after appropriate counseling.

Clinical findings and the results of rapid karyotype for fetuses with three categories of structural malformations are shown in Tables II, III, and IV. Five of 18 fetuses with these structural malformations had chromosomal abnormalities, an incidence of 27.7%. Clinical findings and the results of rapid karyotype in fetuses with IUGR or oligohydramnios are listed in Table V. Three of 13 fetuses with IUGR had chromosomal abnormalities, an incidence of 23.1%.

Comment

The high incidence of chromosomal abnormalities in fetuses with structural malformations is emphasized by our data. Cordocentesis was helpful to obtain rapid karyotype. The finding of abnormal karyotypes in one of seven fetuses with renal or urinary tract abnormalities emphasizes the need to obtain fetal karyotype before any therapeutic shunt procedure is planned. Such procedures have been reported[9] with mixed results. Two of the four cases (Table II) with sonographic features of obstructive uropathy underwent shunt procedures. One procedure was unsuccessful and the patient chose to terminate the pregnancy. The other shunt procedure was successful, but the infant had early neonatal death. One pregnancy was terminated, and one pregnancy resulted in delivery of an infant with bilateral hydronephrosis who is currently doing well at age 20 months.

The increased incidence of chromosomal abnormalities in pregnancies complicated by omphalocele has been emphasized in a previously reported prenatal study.[10] Two of four cases in our study were revealed to have chromosomal abnormalities. Because omphalocele can be corrected postnatally with immediate surgery, but trisomy 18–monosomy 13 can be potentially lethal, the information obtained on fetal karyotype was critical in management decisions with regard to these cases.

Single umbilical artery has been recognized[11] as associated with a high incidence (33.3%) of chromosomal abnormalities. However, this finding is not commonly recognized as an indication to obtain karyotype. Our cases substantiate the previous report and highlight the need for careful evaluation of umbilical cord at obstetric sonography.[12]

Perinatal outcome in pregnancies complicated by

Table V. Findings of IUGR-oligohydramnios cases

No.	*Clinical findings*	*Gestational age (wk)*	*Karyotype*
1	IUGR-oligohydramnios	24	Normal

10	IUGR	31	46,XX,15q−
11	Oligofacial dysmorphic features	32	Normal
12	IUGR-gastrointestinal obstruction	26	69,XXY
13	IUGR-oligohydramnios, hydronephrosis	36	47,XX+21

early IUGR and severe oligohydramnios is extremely poor. If severe oligohydramnios is present without significant IUGR, a diligent search should be made to rule out leakage of amniotic fluid. Careful sonography should be performed to detect any associated structural malformations, but such examination may be hindered by poor visualization because of a lack of fluid. Fetuses with early IUGR or severe oligohydramnios are at increased risk of toxoplasmosis, rubella, cytomegalovirus, and herpes simplex infections, chromosomal abnormalities, and hypoxemia. Evaluation for these parameters can be carried out by obtaining pure fetal blood by cordocentesis. Improved neonatal survival has encouraged obstetricians to intervene for fetal indications at earlier gestational ages. Therefore information on fetal karyotyping is critical in planning management.

As presented in this article, all fetal structural malformations and early cases of IUGR or severe oligohydramnios should be recognized as indications for karyotyping the fetus. This raises a significant dilemma because the majority of these cases are recognized at an advanced gestational age, therefore the option for termination of pregnancy may not be available to the patient. Accordingly, all patients should receive appropriate counseling including discussion of available options before undergoing procedures for the purpose of fetal karyotyping. In our opinion, the primary benefit derived from such testing lies in careful planning of management as it relates to whether cesarean section for fetal distress should be performed. Uniformly lethal chromosomal abnormalities such as trisomy 13 or 18 may be contraindications for performance of cesarean delivery for fetal indications.

Severely isoimmunized pregnancies are very high-risk gestations, frequently requiring transfusion therapy. The finding of one abnormal karyotype of 12 cases highlights the importance of incidental karyotyping of the fetus at the first cordocentesis performed in any isoimmunized pregnancy. Incidental karyotype may also be important in discordant twin gestations, especially if any structural malformation is recognized, as exemplified in our case of monozygotic twins with trisomy 18.

In summary, cordocentesis is helpful to obtain rapid karyotype in cases of fetal structural malformations, IUGR, and nonimune hydrops fetalis, and also may be useful for incidental karyotyping in isoimmunized pregnancies and discordant twin gestations. The karyotype information thus obtained is further helpful in planning clinical management.

Discussion

Dr. Kenneth J. Moise, Jr., Houston, Texas. Since the introduction of the technique of fetal blood sampling by Daffos in France in 1983, cordocentesis has gained widespread acceptance. Although Daffos first used the procedure in the detection of intrauterine fetal infection, further study has revealed the technique to be very useful in other clinical situations in which access to the fetal vascular space is necessary. Data from the

1987 U.S. registry for fetal blood sampling reveals that the predominant indications for the procedure in this country are red cell alloimmunization and cases of chromosomal mosaicism detected by chorionic villus sampling (CVS) or amniocentesis. The authors of the current manuscript have shown a series of cordocenteses for rapid fetal karyotype determination.

My major concern with the manuscript is that the authors fail to address the issue as to when cordocentesis should be used to obtain a rapid fetal karotype. In most centers a fetal karyotype can be obtained by lymphocyte culture within 48 hours. In addition, new culturing techniques for amniotic fluid will produce karotype results in 10 to 14 days. Finally, a direct preparation of chorionic villi obtained by transabdominal CVS will produce karotype results the same day the procedure is undertaken. Rapid karyotype seems to be necessary in two clinical situations. Detection of a fetal anomaly or presentation of a patient at risk of chromosomal abnormalities just before the gestational age at which legal termination of pregnancy can be undertaken represents the first indication for rapid karotype analysis. In this situation, chromosomal analysis obtained by amniocentesis would not return soon enough for the patient to use these results to decide whether to continue a pregnancy. The second indication for rapid karyotype is a situation in which the patient is first seen with fetal anomalies late in the third trimester, when knowledge of an abnormal karyotype would influence obstetric management. Again in this situation, results obtained by amniocentesis may not return before the onset of labor or the detection of fetal distress. An example would be a patient with a newly diagnosed omphalocele at 36 weeks' gestation. If trisomy 18 was found in association with this omphalocele, a vaginal delivery would be preferred.

In Table II of the current manuscript, only one case of renal anomaly was seen at 22 weeks' gestation that may have necessitated fetal blood sampling for rapid chromosome analysis. In addition, two of the eight patients were first seen after 35 weeks' gestation when a karyotype may have influenced obstetric intervention. In Table III, only one of seven patients was first seen at >35 weeks' gestation. In Table IV, none of the four fetuses with umbilical cord abnormalities were first seen at a point in pregnancy when rapid fetal karyotype was necessary for management. Finally, in Table V, only two fetuses were first seen at >35 weeks' gestation. I pose several questions to the authors. First, was transabdominal CVS considered in any of these cases to obtain a rapid karyotype within 24 hours? Second, inasmuch as amniocentesis has a loss rate of approximately 0.5% to 1%, whereas umbilical blood sampling has been reported to have a loss rate from 0.5% to 3.8%, why did the authors chose to use a riskier procedure when in the majority of their cases a rapid karyotype was probably not necessary? What was the authors' loss rate related to cordocentesis in the current series?

My second concern with the presentation involves the recommendation by the authors that fetal blood obtained for other indications such as platelet assessment in the case of immune thrombocytopenic purpura or fetal hematocrit in the case of the alloimmunized pregnancy should be sent for rapid karyotype. One patient of 12 alloimmunized pregnancies was noted to have a chromosomal abnormality. What was the result of this karyotype analysis? Did this patient have any other risk factors that would identify an increased risk for chromosomal abnormalities? Do the authors await the chromosome analysis if fetal thrombocytopenia is detected at cordocentesis before effecting delivery in the pregnant patient with immune thrombocytopenic purpura?

In summary, fetal blood sampling is a useful tool that enables the perinatologist to directly assess the fetal hematologic environment. Rapid karyotype analysis can be undertaken in certain clinical situations when the obstetric decision-making process is influenced by the finding of an abnormal karyotype. To recommend cordocentesis for karyotype analysis at *any* gestational age when a fetal anomaly is detected would appear to be an overutilization of this new and exciting technique.

Dr. Washington Hill, Omaha, Nebraska. I guess the real question for perinatologists and for the physicians in the community is when should the patient be referred for cordocentesis? I would like Dr. Shah to go over that one more time.

Dr. Robert J. Carpenter, Houston, Texas. The issue in this manuscript, which was to have been the main question in doing a rapid karyotype, was the potential benefit. If one takes away the 10 cases of discordant twins, the 12 cases of isoimmunization, six immune thrombocytopenic purpura, and the five others as defined, that removes 33 patients from the series of 101 patients. That then increases to approximately 18% the total positive pickup. That point was not addressed.

Dr. Sharon L. Dooley, Chicago, Illinois. I want to congratulate Dr. Shah on a very nice series. Just to expand a little bit on the safety issue, as our experience with cordocentesis increases our fetal loss rate is going to drop. It is starting to look fairly favorable compared with amniocentesis. However, we should remember that the amniocentesis loss rate that we quote, namely 0.5%, is based on early second-trimester amniocentesis. The risk of a later pregnancy amniocentesis is far lower than that.

Dr. Daniel A. Rightmire, Springfield, Illinois. Are there data that address the frequency with which the 8- to 10-day difference between rapid karyotyping from fetal blood sampling and from amniocentesis has proved to be of benefit to the patient or the physician? That is really the issue in rapid karyotyping.

Dr. Judith A. Ney, Rochester, Minnesota. It seems to me that the loss rate is certainly crucial here and the questionable clinical usefulness of rapid karyotyping at these gestational ages has been commented on, but the other issue is the morbidity of the procedure. How many of these patients required emergency cesarean section at a gestational age of 26 weeks because the procedure was performed?

Dr. Shah (Closing). Dr. Moise and the various members have raised some very pertinent questions.

As to the question of transabdominal CVS in these cases that were subjected to rapid karyotyping, I think one should keep in mind that not all cases are amenable to CVS and that cordocentesis may be an easier procedure. This would be an issue in cases with posterior placentas, all the more so if there is the presence of oligohydramnios or structural malformation that may interfere. Also, we do not have an ongoing program of transabdominal CVS. However, it must be added to the armamentarium available to the perinatologist for patients who may require rapid karyotyping.

As far as electing to perform cordocentesis for rapid karyotyping over amniocentesis is concerned, several issues need to be addressed. First, many of these patients are referred to our center not necessarily for cordocentesis but for other clinical circumstances, including preterm labor or severe fetal heart rate abnormalities. Adjunctive indications for obtaining fetal blood may exist, such as gas analysis or typing of human leukocyte antigen for diagnosis of zygocity. In cases of preterm labor the need to obtain the fetal karyotype results in a shorter time is heightened.

I think it is important that patients for whom such clinical circumstances are not present be offered all the diagnostic options available to them, including amniocentesis. This was done in all cases by a genetic counselor (who is also the coauthor of the manuscript) who independently counseled all the patients and offered them the option of amniocentesis.

It is interesting to note that the majority of the patients nevertheless accepted rapid karyotyping by cordocentesis over amniocentesis. This may be essentially a reflection of anxiety on the part of the mother who has not only discovered that there is another perinatal problem, but that a serious fetal abnormality or other concerns may be present.

As far as the risk/benefit ratio is concerned, amniocentesis is considered as having a $\leq 0.5\%$ risk when performed in the third trimester. Even so, it is offered in certain cases in which the chance of finding an abnormal karyotype is very low. If one were to readjust the data and selectively address the issues of fetal structural malformations, IUGR, nonimmune fetal hydrops, discordant twins, and advanced gestational-maternal age, one gets numbers as follows: 78 cases with 11 abnormal karyotypes, for an abnormal karyotyping incidence of 13.7%. This certainly would be significant in the patient's decision-making process and should enter into the counseling process as far as the risk/benefit ratio is concerned.

As far as the case of isoimmunized pregnancy is concerned, I have already addressed the results of the karyotype. This fetus did not have other structural malformations detected on careful sonographic examination. The results of the rapid karyotype returned as mosaic 45,X/46,X, ring form X as previously stated, essentially a 45,X or X monosomy. The patient was counseled about the results, and after counseling with regard to the outcome of this fetus, also underwent intrauterine fetal transfusions as indicated for the isoimmunized process. We do not consider isoimmunization per se as an indication to obtain karyotyping. However, before embarking on complex and invasive management, consideration should be given to assuring the chromosomal normalcy of the fetus.

As far as the cases of immune thrombocytopenia are concerned, many of these patients were referred into our center; and the cesarean delivery was planned adequately remote from the time of the cordocentesis. Rapid karyotyping was performed from a sample of convenience, and we do not advocate this for routine management.

With regard to the question by Dr. Hill as to when clinicians should refer patients for cordocentesis, my response is that clinicians should refer patients for primary clinical considerations, which are the usual common perinatal conditions that require referral, such as premature labor and fetal structural malformations. I think the decision as to what diagnostic options should be offered to the patient is best left in the hands of the people who counsel these patients and offer all the options on a routine basis and therefore are better able to explain to the patient the various considerations involved in these cases. Therefore, I do not have any specific list of indications for which physicians should refer patients for cordocentesis.

However, the cases presented here heighten concerns with regard to many of the fetal structural malformations, an example being the single umbilical artery. Even though this malformation was recognized previously to be associated with chromosomal abnormalities, it is not usually addressed in a sonography report. I believe it should be addressed routinely in a sonography report so that this information can be used in management.

Dr. Carpenter's comments about higher pickup rate are very pertinent if we consider only the population with specific indications. If we eliminate 23 samples of convenience, then the 78 patients with specific indication had 11 abnormal test results, a rate of 13.7%.

As far as Dr. Dooley's question with regard to the risks of amniocentesis is concerned, I agree with her that the risk of amniocentesis in our hands is far less than what is commonly cited from the literature or from the U.S. collaborative data. In the third trimester the risk would be expected to be even lower, and this should be explained to the patient as far as her diagnostic options are concerned.

In response to Dr. Rightmire's question with regard to the primary benefit to the patient, I think all the issues that we discussed, in terms of having knowledge about the normal karyotype and appropriately preparing the mother for the possibility of abnormal karyotype results and their influence on clinical decision making, are important considerations.

With regard to the question of morbidity in these cases and the question of fetal loss rate that Dr. Moise raised, there was one fetal loss in this total group of

101 cases. This was a case at 17 weeks' gestation with severe oligohydramnios and suspected renal agenesis. The patient also underwent instillation of indigo carmine dye and had a tetanic uterine contraction with rupture of membranes. This fetus was the only one lost in this series. The patient subsequently elected to complete the process of abortion with prostaglandin.

As far as the question of morbidity is concerned, there was not a single case of fetal distress or emergency cesarean section that was related to the procedure itself in this series.

The effect of prolactin on murine in vitro fertilization and embryo development

William G. Dodds, MD, Jeffrey Fowler, MD, Amy Peykoff, BS,* Kurt F. Miller, PhD, Chad I. Friedman, MD, and Moon H. Kim, MD

Columbus, Ohio

Elevated levels of serum and follicular fluid prolactin occur in women undergoing ovulation induction with both clomiphene citrate and gonadotropin therapy. Prolactin's effect on oocyte fertilization and embryo cleavage has not been fully characterized. Using a murine model, we investigated the effect of prolactin on in vitro fertilization and subsequent embryo cleavage in media containing 150, 400, and 600 ng/ml purified mouse prolactin. No difference was found in fertilization rates when compared with control rates. Culture of both in vivo and in vitro fertilized two-cell embryos in murine prolactin at 150, 400, and 600 ng/ml showed no significant difference in blastocyst, morula, or embryo degeneration rates when compared with control rates. An assay for binding of murine prolactin to spermatozoa, oocytes, and the embryo at various cleavage stages revealed no specific murine prolactin binding. These in vitro experimental results fail to show a role for murine prolactin in effecting mature oocyte fertilization or subsequent embryo cleavage. The lack of binding of murine prolactin to the gametes and early developing embryo supports the in vitro findings. (Am J Obstet Gynecol 1990;162:1553-61.)

Key words: Prolactin, in vitro fertilization, embryo cleavage

The mammalian oocyte enters the first meiotic division and arrests in diplotene prophase during fetal life. Oocytes remain in the dictyate stage until shortly before ovulation when meiotic competence is obtained and the first meiotic division is completed. A large amount of experimental data supports the primary importance of follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin as major regulators of follicle development and oocyte maturation.

Prolactin has been shown to have an inhibitory effect on both rat and human granulosa cell estrogen and progesterone synthesis.[1, 2] In addition to its action on granulosa cell estrogen and progesterone synthesis, ovine prolactin has been found to stimulate granulosa cell production of oocyte maturation inhibiting factor.[3] One study indicates that oocyte maturation inhibiting factor may in fact be an enzyme-clipped oligopeptide fragment of prolactin.[4] Through its modulating action on estrogen and progesterone synthesis and oocyte maturation inhibiting factor activity, prolactin probably plays a significant role in oocyte maturation. Its role, if any, in fertilization and early embryo development is less well defined.

Several investigators have examined follicular fluid human prolactin levels in women undergoing ovulation induction for in vitro fertilization and have found that lower mean levels are positively associated with oocyte fertilization.[5, 6] In contrast, other studies correlated higher follicular fluid human prolactin levels in preovulatory follicles with oocyte fertilization.[7, 8] Another

study measured bioactive follicular fluid human prolactin levels by use of an Nb2 lymphoma cell bioassay together with immunoreactive human prolactin levels and found no correlation between bioassay or immunoreactive follicular fluid human prolactin levels and oocyte fertilization.[9]

Murine in vitro fertilization and embryo development experiments with prolactin have yielded equally conflicting reports. An initial study indicated that ovine prolactin, at a level of 100 ng/ml, inhibited in vitro progression of murine two-cell embryos to blastocyst.[10] A subsequent study, evaluating murine prolactin levels up to 100 ng/ml, failed to find any effect of murine prolactin on two-cell embryo to blastocyst development in vitro.[11] However, these authors reported that when spermatozoa were incubated with culture media supplemented with 100 ng/ml of murine prolactin, there was a reduction of in vitro fertilization capacity. With the recognition that mouse serum prolactin levels of 100 ng/ml represent low estrous levels, a more recent study evaluated ovine prolactin levels up to 1000 ng/ml.[12] This group reported improved in vitro mouse two-cell embryo to blastocyst development with supraphysiologic ovine prolactin media supplementation.

The purpose of our study was to evaluate the in vitro effect of murine prolactin on fertilization and subsequent embryo development with a homologous murine model. This study was designed to examine physiologic and supraphysiologic murine prolactin effects. Additionally we investigated spermatozoa, oocytes, and the preimplantation embryo for specific murine prolactin binding.

Material and methods

Animals. Sexually mature CB6F1 female mice, 8-12 weeks of age (Charles River Laboratories, Wilmington, Mass.) were used in both the in vivo and the in vitro fertilization experiments. The CB6F1 mouse is a hybrid cross between BALB/c and C57B1/6 strains. Oocytes from this hybrid F1 mouse have consistently provided in vitro fertilization rates of 70%. Individually housed 4- to 6-month-old CB6F1 male mice (Charles River Laboratories) were used in all experiments. Ovulation induction was carried out in standard fashion with female mice receiving 5.0 IU of pregnant mare serum gonadotropin (Sigma Chemical Co., St. Louis) intraperitoneally followed by 5.0 IU of human chorionic gonadotropin (hCG) (Sigma Chemical Co.) intraperitoneally 48 hours later.

Culture media. Fresh Whitten's medium was prepared as described elsewhere for both fertilization and embryo culture.[13] The medium was adjusted to an osmolarity of 278 ± 2 mOsm/L. Whitten's medium used for in vitro fertilization was supplemented with 30 mg/ml bovine serum albumin (ICN Immunobiologicals, Lisle, Ill.). Whitten's medium that was used for embryo culture (designated as the growth medium) was supplemented with 3 mg/ml bovine serum albumin. The fertilization and growth media were adjusted to a pH of 7.4 after equilibration in a 5% carbon dioxide–air incubator at 37° C. All media were filter sterilized immediately before use. In vitro fertilization and embryo cultures were carried out in 60 × 15 mm welled Falcon culture dishes (Becton Dickinson & Co., Oxnard, Calif.) in a humidified 5% carbon dioxide–air incubator at 37° C.

Purified murine prolactin in lyophilized form was graciously provided by Dr. A. F. Parlow, Director of the Pituitary Center at Harbor–University of California Los Angeles Medical Center. A fresh stock solution of murine prolactin was made for each experiment by dissolving 10.0 μg of the murine prolactin in 5 ml of Whitten's growth medium.

In vitro fertilization. Female mice were put to death by cervical dislocation 14 to 16 hours after hCG injection. The cumulus masses were dissected from the oviducts and immediately placed in Whitten's fertilization medium. A minimum of eight female animals were put to death for each experiment to provide sufficient oocytes to simultaneously test each concentration of murine prolactin. Cumulus masses were pooled and randomly assigned to the different murine prolactin test concentrations or unsupplemented control fertilization media. One cumulus mass was cultured per welled Falcon culture dish. For each experiment there were four culture dishes each for control and 150, 400, and 600 ng/ml murine prolactin test concentrations. The in vitro fertilization experiments were repeated three times and results were pooled for analysis. The murine prolactin concentrations studied were based on results of serum murine prolactin levels that we have assayed in this strain of mouse. We found that CB6F1 female mice had a mean estrous prolactin level of 124 ± 32 ng/ml (range 78 to 180) while pregnant mare serum gonadotropin– and hCG-stimulated mice had a mean serum prolactin level of 220 ± 83 ng/ml (range 102 to 450). Prolactin concentrations were set at 150, 400, and 600 ng/ml to test prolactin at normal physiologic, ovulation induction, and supraphysiologic levels.

Male mice were put to death by cervical dislocation. The caudal epididymides were removed and placed in Whitten's fertilization medium. Sperm was extruded from each epididymis by gently squeezing the epididymis with watchmen forceps. The sperm suspensions were immediately placed in the 5% carbon dioxide–air incubator at 37° C. Sperm suspensions were examined at 10 minutes for the presence of whirlpool-like formations on the surface. Sperm count and motility were

assessed immediately before insemination of dishes. Approximately 0.5 × 10^6 motile sperm was added to each fertilization dish, which contained 10 to 20 oocytes. Ova and sperm were incubated together for 6 hours in control or murine prolactin–supplemented fertilization dishes containing 150, 400, or 600 ng/ml of murine prolactin. At the end of 6 hours the oocytes were washed twice and transferred to growth media supplemented at the same murine prolactin concentration as that in the respective fertilization media. All morphologically abnormal oocytes were discarded. This represented between 5% and 10% of oocytes collected. Dishes were examined at 24 hours for fertilization (defined at the two-cell stage). For each murine prolactin test level the even-two-cell embryos were then randomly divided, with half transferred to growth media of similar murine prolactin concentration while the other half were transferred to unsupplemented growth media. At 96 hours the numbers of blastocysts, morulas, two-to-eight cell embryos, and degenerated embryos were recorded. For each concentration of murine prolactin 126 to 188 oocytes were tested.

In vivo fertilization. Female mice were caged with male mice of proved fertility after receiving an hCG injection at 4 PM. In the morning mating was confirmed by observation of a vaginal plug. The female mice were removed from the mating cages and housed together. Female mice were put to death by cervical dislocation 48 hours after hCG administration. Two-cell embryos were collected from the dissected oviducts with abnormal embryos discarded. Abnormal embryos, including degenerating and uneven two-cell embryos, represented between 5% and 10% of all embryos. The two-cell embryos from six to eight female mice were pooled and randomly distributed. Experiments were run in parallel fashion with 0, 150, 400, and 600 ng/ml of media supplemented with murine prolactin. Embryos were transferred to fresh media every 24 hours. After 72 hours the numbers of blastocysts, morulas, two-to-eight-cell embryos, and degenerated embryos were recorded. The in vivo fertilization experiment was performed on three separate occasions to achieve a minimum of 75 even-two-cell embryos included for each group tested.

Radioiodination and binding of mouse prolactin. Purified murine prolactin (AFP 6476C) was radioiodinated by use of iodogen (Pierce, Rockford, Ill.) as previously described (30 μCi/μg).[14] Specific binding of murine prolactin labeled with iodine 125 to gametes was evaluated by the addition of 100,000 cpm of labeled murine prolactin to gametes or embryos in the presence or absence of a 100-fold excess of unlabeled murine prolactin. Approximately 50,000 spermatozoa and 100 oocytes and embryos at the two-cell, four-to-eight-cell, morula, and blastocyst stages each were tested. Incubations were done in 25 μl of phosphate-buffered saline solution containing 0.1% bovine serum albumin. After 2 to 4 hours at 37° C, the incubation was terminated by the addition of 2 ml of cold phosphate buffered saline solution and centrifugation. The supernatant was aspirated, and the precipitate was washed and counted. Specific binding was defined as those counts that were displaced by the addition of unlabeled murine prolactin. As a positive control, iodinated murine prolactin was incubated with a preparation of rat liver membrane in the presence or absence of excess unlabeled murine prolactin.

Statistical analysis. Transformation rates of in vivo fertilized two-cell embryos to blastocysts were analyzed by χ^2 test. In vitro fertilization rates between groups were also analyzed by χ^2 test. Log linear analysis was used for three-dimensional contingency table comparison of embryo development from the in vitro fertilized oocytes as a function of the different murine prolactin concentrations and time of murine prolactin exposure.

Results

In vivo fertilization. The effect of increasing concentrations of murine prolactin on two-cell embryo to blastocyst transformations and percent degeneration is shown in Fig. 1. Blastocyst formation determined at 72 hours in the control group was 70%, while embryo degeneration rate was 14%. As seen in Fig. 1, embryos exposed to 150, 400, and 600 ng/ml murine prolactin had blastocyst transformation and embryo degeneration rates similar to those of the control group. There was no significant difference in the embryo development profile when blastocyst, morula, two-to-eight-cell, and degenerated embryo transformation rates of test murine prolactin concentration groups were compared with control rates.

In vitro fertilization. Oocytes were exposed to physiologic and supraphysiologic levels of murine prolactin during the time of fertilization and subsequent embryo development. These were compared with unsupplemented controls. The fertilization rate defined at the two-cell cleavage stage was 73% in the control group. Table I summarizes the fertilization rates for the study and control groups. As can be seen, there was no statistically significant difference in fertilization rates between the murine prolactin and control groups. Fig. 2 summarizes the subsequent embryo development of the in vitro fertilized oocytes. As depicted in Fig. 2, the rate of blastocyst transformation and embryo degeneration was similar between the initial 24-hour-only and 96-hour murine prolactin exposure groups and control. A comparison of development of all embryos was made by categorizing stage of development into blastocyst, morula, two-to-eight-cell embryos, and degenerated

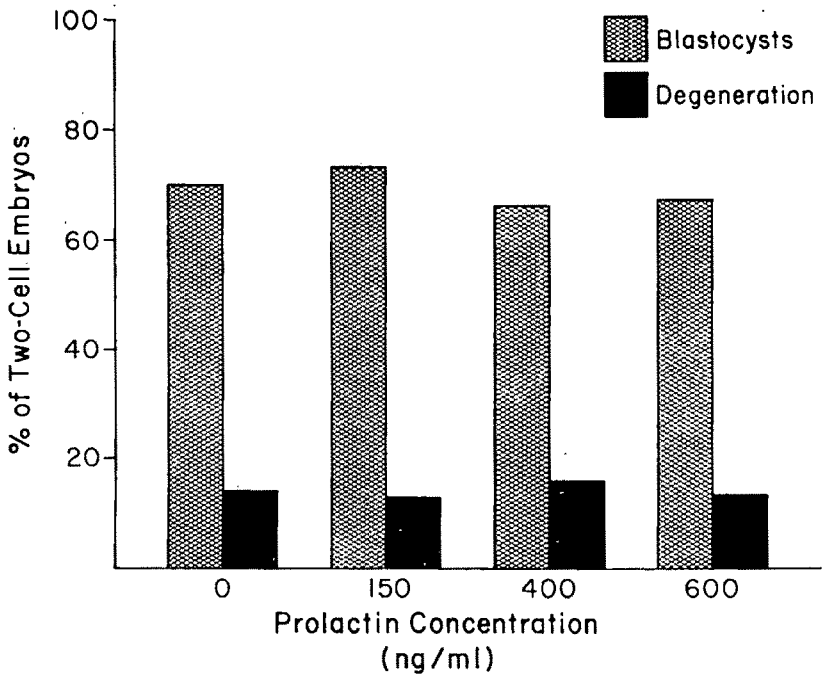

Fig. 1. Effect of murine prolactin on the development of mouse oocytes fertilized in vivo. Two-cell embryos in test groups were cultured in murine prolactin–supplemented media for 72 hours.

Table I. Effect of marine prolactin on in vitro fertilization rates

Prolactin concentration (ng/ml)	*Fertilized*		*No. of oocytes*
	No.	*%*	
0	120	73	165
150	86	68	126
400	134	71	188
600	91	68	133

embryos. Log linear analysis revealed no statistical difference in these stages of embryo development between 24-hour murine prolactin, 96-hour murine prolactin, and control groups.

Binding of murine prolactin. There was no specific binding to spermatozoa, oocytes, or embryos. On incubation with 100,000 cpm of murine prolactin labeled with ^{125}I, between 5% and 15% of the radioactivity was associated with the cells at the end of the incubation. However, the percentage was not altered by the addition of a 100-fold excess of unlabeled murine prolactin. The rat liver membrane preparation was found to specifically bind 27% of the labeled murine prolactin.

Comment

Clinical studies evaluating follicular human prolactin levels in women undergoing in vitro fertilization have yielded conflicting results concerning follicular fluid human prolactin concentration and its relationship to oocyte fertilization.[5-8] Two studies reported a negative association between follicular fluid human prolactin levels and oocyte fertilization.[5,6] In contrast, other studies found that high follicular fluid human prolactin levels seemed to correlate with oocyte fertilization.[7,8] Studies evaluating the effect of ovine prolactin and murine prolactin on mouse in vitro two-cell embryo to blastocyst progression have also revealed conflicting results.[10,12] To our knowledge, this study represents the first in vitro study of physiologic and supraphysiologic murine prolactin concentrations on in vitro fertilization and subsequent embryo development. The results reported here suggest no significant effect of murine prolactin at physiologic or supraphysiologic levels on mouse in vitro fertilization or subsequent embryo development. The murine prolactin concentrations, as stated earlier, reflect the physiologic range of serum murine prolactin levels seen during estrus in CB6F1 mice (78 to 180 ng/ml), during pregnant mare serum gonadotropin stimulation in this strain (102 to 450 ng/ml) and the supraphysiologic range (600 ng/ml). While serum prolactin levels do not necessarily reflect prolactin concentrations in the fallopian tube, there have been several human studies demonstrating the close correlation between follicular fluid and peritoneal fluid human prolactin compared with serum concentrations.[15,16] Since the mouse fallopian tube encapsulates its ovary, it was felt that if serum and follicular fluid murine prolactin levels are closely approximated,

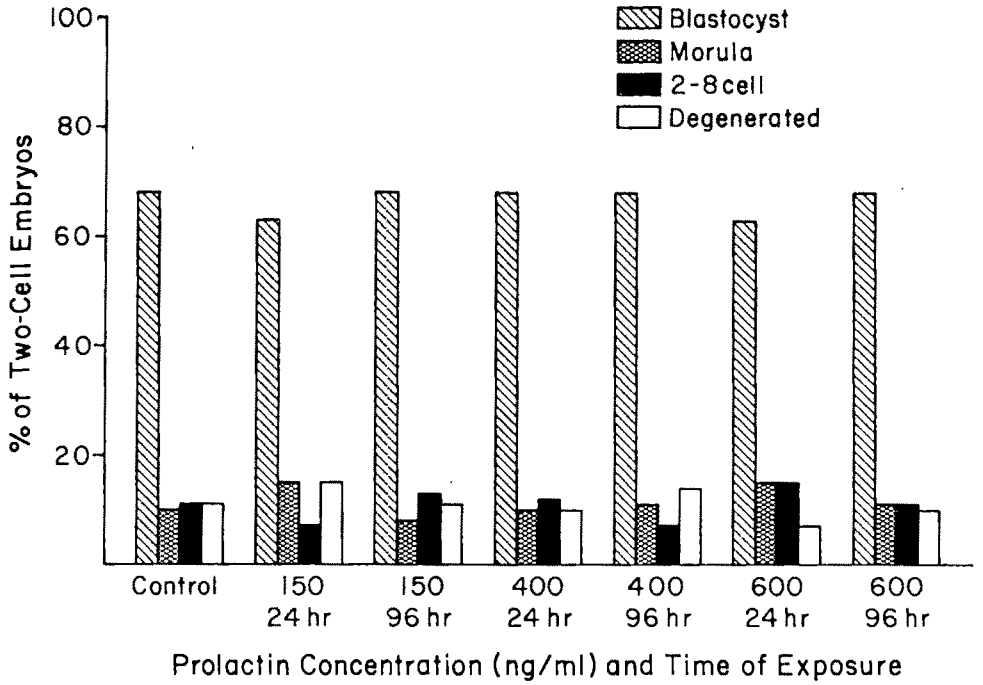

Fig. 2. Effect of murine prolactin exposure on embryo development from oocytes fertilized in vitro. Oocytes were fertilized in murine prolactin–supplemented media. At 24 hours half the fertilized two-cell embryos were transferred to unsupplemented Whitten's media with the other half transferred to fresh murine prolactin media. At 96 hours both 24-hour and 96-hour murine prolactin exposure groups were evaluated.

as is seen in humans, then the murine prolactin concentration in the fallopian tube would probably also approximate the serum concentration after follicle rupture.

The lack of any in vitro inhibitory or stimulatory effect of purified murine prolactin on fertilization or two-cell embryo to blastocyst development suggests that, in the mouse, murine prolactin has no direct postovulatory effect on the oocyte or early embryo. These findings differ critically from those of Fukuda et al.[11] and Yohkaichiya et al.[12] Yohkaichiya et al.[12] reported an improved in vitro rate of blastocyst and hatched blastocyst development from in vivo fertilized mouse embryos when cultured in ovine prolactin concentrations of 100 to 1000 ng/ml.[12] However, the blastocyst transformation rate in their study was unusually low in both the supplemented media control group (20%) and the test groups with ovine prolactin concentrations <100 ng/ml (20%), making interpretation difficult. Additionally they tested ovine prolactin rather than murine prolactin. As reported here Fukuda et al.[11] found no effect of murine prolactin on mouse two-cell embryo to blastocyst development; however, they reported a decrease in the in vitro fertilization rate when spermatozoa were preincubated in culture media containing 50 and 100 ng/ml murine prolactin concentrations. In their study Fukuda et al.[11] defined fertilization at the male pronuclei level and not at the two-cell cleavage stage. They found no difference from control in the motility rates of epididymal spermatozoa preincubated with murine prolactin and had no explanation for the decreased in vitro fertilization capacity of these spermatozoa. In our experiment spermatozoa were first preincubated in unsupplemented media and then combined with fresh oocytes in control or murine prolactin–supplemented fertilization media. In this setting we found no in vitro effect of murine prolactin on the spermatozoa's fertilization capacity as defined at the two-cell cleavage stage.

Consistent with our in vitro results, we found no evidence of murine prolactin binding to spermatozoa, the oocyte, or the early embryo. It must be acknowledged that the radiolabeled murine prolactin assay used for receptor detection is probably not sufficiently sensitive to detect receptors at low concentrations. Experiments with more sensitive receptor analysis techniques would be needed to evaluate the possibility of a low number of murine prolactin receptors on either the gametes or early embryo.

Clearly prolactin has been shown to be an important gonadotropin regulator of ovarian follicle development. It is well known that hyperprolactinemia can disrupt ovarian follicle development and corpus luteum function, resulting in menstrual cycle disorders

including luteal phase defect, anovulation, and infertility.[17] Centrally prolactin increases hypothalamic dopaminergic and opioid tone, which may affect LH and FSH secretion by inhibiting pulsatile secretion of gonadotropin-releasing hormone.[18] Prolactin also has direct ovarian actions that include inhibition of FSH-induced aromatase activity in rat granulosa cells[19] and in vitro suppression of progesterone production from human granulosa cells.[1] Of potentially greater significance, Channing and Evans[3] have shown that ovine prolactin will stimulate in a dose-dependent fashion porcine granulosa cell release of the nonsteroidal oocyte maturation inhibition factor. The role of prolactin in maintenance of meiotic arrest has been further substantiated in studies by Baker and Hunter[20] and Nolin.[4, 21] Baker and Hunter[20] have demonstrated that antiprolactin serum induced oocyte meiotic maturation in cultured porcine follicles. Subsequently Nolin[21] demonstrated the presence of rat prolactin in both granulosa cells and the dictyate oocyte. Nolin[4] noted that the availability of rat prolactin for oocyte uptake was dependent on transcellular transport from the granulosa cell, probably via the thin processes that project from cumulus cells through the zona pellucida to contact the oolemma at gap junctions. With anti–rat prolactin antisera, molecular homology between purified pituitary rat prolactin and oligopeptides in Channing's oocyte maturation inhibition factor follicular fluid fraction also has been demonstrated. Nolin[4] hypothesized that the role of prolactin in maturation inhibition may be analogous to a corticotropin-like intermediate lobe peptide theory of peptide hormone action in which prolactin acts as a parent polypeptide that undergoes cleavage by target cell proteases into small oligopeptide fragments, which are the responsible agents in the inhibition of maturation. Since cumulus cells in mice, as well as humans, remain in contact with the oocyte during fertilization, it seemed clearly possible that prolactin or an oligopeptide fragment of prolactin also may act in a regulatory fashion after ovulation to affect oocyte fertilization or early embryo cleavage. It was for this reason that we felt it important to study cumulus-intact mouse oocytes.

The lack of an in vitro effect of murine prolactin on fertilization and early mouse embryo development does not eliminate the possibility of an in vivo role. Osmoregulatory actions of prolactin in euryhaline fish, in the chick embryo, and in transport of water across the human amnion are well known. It may be that prolactin acts in an osmoregulatory fashion at the level of the fallopian tube and endometrium to maintain the proper milieu for fertilization and embryo development. It is also possible that in vivo prolactin gives rise to regulatory oligopeptides within the fallopian tube or at the level of the endometrium that could affect in vivo fertilization, embryo development, or implantation. The present in vitro study cannot rule out these possibilities.

In conclusion, this study demonstrates that murine prolactin at physiologic and supraphysiologic levels had no adverse effects on in vitro fertilization and embryo development in the mouse. The absence of murine prolactin receptors on the gametes and early embryo is consistent with these findings. Species differences with respect to prolactin action on gametes and/or early embryo development may clearly exist. However, recent clinical studies in women undergoing in vitro fertilization procedures also support no effect of elevated serum prolactin levels on subsequent in vitro fertilization, embryo cleavage, or pregnancy rate.[22] In addition, human amniotic fluid with its known high human prolactin concentration has been successfully used as fertilization and embryo growth media for both mouse and human in vitro fertilization.[23] These data further corroborate the findings in our study. It should be cautioned that our study did not address the potential negative effect of oocyte exposure to elevated midcycle prolactin levels before ovum release. Further characterization of the actions of prolactin as a reproductive hormone will require investigation of potential in vivo effects of prolactin on embryo development, tubal transport, and implantation.

We thank Dr. Larry Sachs for his assistance with the statistical analysis.

Discussion

Dr. Marguerite K. Shepard, Indianapolis, Indiana. The effect of elevated levels of prolactin on ovarian function in regularly cycling women has been a source of investigation for some years. While initial reports associated hyperprolactinemia with luteal phase abnormalities,[1] subsequent studies have shown that prolactin affects follicular phase events as well. Not only the pattern of follicle development is affected by prolactin levels[2] but also intrafollicular events such as aromatase activity[3] and LH receptor formation.[4] Conflicting reports on the effect of systemic and follicular fluid levels of prolactin on the outcome of in vitro fertilization cycles have led to this study. In a broader sense this article addresses the role of prolactin in the immediate postovulatory phase of the cycle.

Dr. Dodds and his co-workers have specifically investigated the direct effect of prolactin on gametes, the fertilization process, and early embryonic development on the CB6F1 mouse. This strain was chosen because it is used commonly to test culture medium for use in human in vitro fertilization. They have attempted to correct the deficiencies noted in previous studies by continuing their cultures through the immediate preimplantation phase of embryonic development. They have included embryos from both in vivo and in vitro fertilization to control for the effects of fertilization environment on embryonic development, and a crossover segment addresses the effect of prolactin in the tubal fluid on the development of preimplantation embryos. Their successful fertilization rate is in the range reported for the CB6F1 mouse.

Their study design includes adequate numbers of observations of each time point for meaningful data to be accumulated. The time period encompassed by the study includes the postovulatory, preimplantation phase of the cycle when the effect of elevated prolactin would necessarily be a direct one on the gametes and embryos rather than on the support system, including the follicle, the corpus luteum, and the endometrium.

Their results consistently fail to demonstrate any direct effect of prolactin in the fluid medium surrounding the gametes and developing embryos on the fertilization rate or subsequent embryo development when compared with controls.

The major problem in extrapolating these data to normal periovulatory events is the lack of a control group involving unstimulated mice or a mouse strain that does not show a physiologic rise in prolactin at the midcycle. Cutie and Andino,[5] using cultured human granulosa cells, have shown a threshold effect of prolactin on inhibition of FSH-mediated steroid biosynthesis with no further inhibition with increasing levels of prolactin. Since all of the mice were pregnant mare serum gonadotropin–hCG stimulated, all oocytes were presumably exposed to an elevated level of endogenous prolactin before retrieval. Would the fertilization rate have been higher than 70% if such exposure had not occurred or if exposure to lower levels of endogenous prolactin had occurred as seen in spontaneous cycles?

The absence of prolactin binding to the gametes or embryos may answer this question, but as the authors point out, their techniques don't eliminate the possibility of low-level receptor formation.

The extrapolation of these data to human periovulatory events and in vitro fertilization outcome is confounded by the fact that a periovulatory increase in prolactin with gonadotropin stimulation does not occur consistently in women and such rises have been asso-

ciated with a poor outcome in regard to successful pregnancy in in vitro fertilization cycles.

Nonetheless, the observations made by Dr. Dodds and his co-workers have made a valuable contribution to our understanding of the role of prolactin in the immediate postovulatory period. It will be of interest to learn of their proposed approach to elucidate further the preovulatory and postfertilization effects of elevated prolactin on oocytes and developing embryos.

DR. MARTIN M. QUIGLEY, Cleveland, Ohio. Prolactin is a ubiquitous hormone with a multitude of effects on the reproductive system. The role of intrafollicular prolactin on subsequent fertilization in vitro, embryonic development, and subsequent pregnancy establishment is very much an open question. Some authors[1, 2] have reported increased rates of fertilization and pregnancy establishment in the presence of elevated intrafollicular prolactin. Others[3, 4] have reported decreasing follicular fluid levels of prolactin with increasing oocyte maturation and a better fertilization rate with lower levels of intrafollicular prolactin. Yet additional investigators[5, 6] have shown no relationship between follicular fluid prolactin levels and fertilization.

This study from The Ohio State University uses a mouse system to examine the effect of supplementation of the culture media with superphysiologic levels of prolactin on the success of in vitro fertilization and subsequent embryonic development in vitro. In addition, the effects of prolactin on the in vitro embryonic development of in vivo fertilized oocytes also are studied.

The authors' results are very similar to the prior publication of Fukuda et al.[7] In that study lower levels of prolactin (10 to 100 ng/ml) were used as culture supplementation, compared with the 150 to 600 ng/ml used in this study. The Fukuda study demonstrated that preincubating spermatozoa in culture media with elevated prolactin during their period of capacitation decreased, in a dose-dependent fashion, the fertilization rates. However, when spermatozoa were capacitated in prolactin-free media before being transferred into prolactin-supplemented media, the fertilization rates were uniformly slightly decreased in the prolactin-supplemented culture media, when compared with prolactin-free media. This effect was independent of the prolactin level in the media. A similar finding was not noted by Dr. Dodds and his associates. In both studies, however, subsequent embryonic development of oocytes fertilized in high-prolactin media, as well as the in vitro embryonic development of oocytes fertilized in vivo, was unaffected by the level of prolactin in the embryo growth culture media.

The real question, which neither the Fukuda study nor the present study was able to answer, is what effect elevated levels of prolactin during folliculogenesis and oocyte maturation have on subsequent fertilization and embryonic development. I believe this study demonstrates quite conclusively that elevated levels of prolactin have little, if any, impact on fertilization or postfertilization events. However, there remains the possibility that elevated prolactin levels in the culture media would adversely effect pregnancy establishment and outcome. A definitive answer to that question would require that the embryos exposed to elevated prolactin levels be transferred to pseudopregnant recipients and the pregnancy outcome monitored. However, that procedure is difficult and time consuming and the information gained probably would not be worth the investment in time and effort.

The question that really needs to be addressed is the role of elevated prolactin on oocyte maturation. A recent report[8] studied the effect of culture media supplementation with various protein and steroid hormones during oocyte maturation in vitro. These investigators demonstrated that the supplementation with prolactin (10 to 1000 ng/ml) enhanced, in a dose-dependent fashion, the subsequent embryonic development of these oocytes after fertilization in vitro. They postulated that both estradiol and prolactin played key roles in the promotion of preimplantational embryonic development.

The authors are to be congratulated for a well-designed and well-presented study. However, this investigation is but the first step in the clarification of the role of prolactin and fertilization.

Dr. Robert W. Rebar, Cincinnati, Ohio. I wonder if I might just take a moment to speculate to or for Dr. Dodds and see what his reaction is. As Dr. Quigley noted, prolactin is a hormone that has been in search of a function for many years. More than a hundred functions have been ascribed to this hormone, and clearly we don't really know what it does under a lot of circumstances.

The one interesting observation that I think has been borne out is the fact that prolactin does alter glucose metabolism such that the response to glucose and the release of insulin are altered. I've always been amazed therefore that this particular field has not asked this question: Is there an indirect role for prolactin given the fact that we now know that insulin-like growth factor I receptors and insulin receptors play important roles within the follicle.

I have not seen any data addressing this particular question. Yet this might be one particular area of interest, particularly since there always has been the question about what prolactin could be doing during the follicular phase and particularly in the periovulatory phase of the cycle.

Dr. Dodds (Closing). First I would like to respond to Dr. Shepard's comment about the lack of oocyte retrieval from spontaneous cycling mice for an in vitro fertilization control. She is correct that mice in all of our experimental groups were stimulated with pregnant mare serum gonadotropin. We did not run a nonstimulated control; however, within our laboratory we have found no difference in the pregnant mare serum gonadotropin and natural cycle group with respect to fertilization and embryo development success. Pregnant mare serum gonadotropin stimulation simply increases the oocyte yield per mouse put to death.

In response to Dr. Quigley's comments, I agree that clinical studies that have tried to examine the relationship between prolactin and oocyte fertilization and embryo development are conflicting. His reference to the recent article from Dr. Wallach's group by Dr. Yoshimura concerning the effect of prolactin and estrogen on in vitro oocyte maturation brings up several important points. As Dr. Quigley has mentioned, Yoshimura has reported that the addition of prolactin and estrogen to in vitro oocyte maturation media did nothing to fertilization success; however, subsequent morula and blastocyst development was greatly increased. It is important to note that Dr. Wallach's group focused on gonadotropin, estradiol, and prolactin effects on in vitro maturation of immature oocytes and their subsequent fertilization and development. In contrast, we collected mature oocytes and studied the effect of prolactin on the fertilization and preimplantation embryo development. The results of the two studies are not contradictory. I think our study documents prolactin's lack of effect on mature oocyte fertilization and subsequent development while Yoshimura's study indicates prolactin is important in in vitro oocyte maturation.

The thing I found most interesting about Dr. Yoshimura's article was, as Dr. Quigley has mentioned, prolactin's improvement of morula and blastocyst transformation only when estrogen supplementation also was present. The unresolved problem that I have is that the studies by Channing and Nolin indicate that prolactin stimulates oocyte maturation inhibiting factor. In particular Channing has shown that prolactin stimulates porcine granulosa cell release of oocyte maturation inhibiting factor. In addition, Nolin reported homology between Channing's oocyte maturation inhibiting factor and prolactin. From this work, Nolin postulated that oocyte maturation inhibiting factor may be just an oligopeptide fragment of the prolactin molecule. In other words prolactin may be the parent molecule of oocyte maturation inhibiting factor. If prolactin does increase oocyte maturation inhibitor, it remains to be explained how prolactin functions in vitro apparently to improve oocyte maturation and subsequent preimplantation embryo development.

I agree with Dr. Quigley's comments that the role of prolactin in oocyte maturation will require further clarification. An in vivo model to address this issue would be optimum. In terms of Dr. Rebar's comment, I agree that prolactin may affect glucose metabolism; however, I do not know of any studies that have addressed that issue in the oocyte. It would be an interesting area to explore.

Another area that we are interested in is prolactin's potential role in stimulating lymphocytes. Prolactin may be important in stimulating endometrial lymphocytes that help the endometrium to become prepared to allow implantation. The effect prolactin may have on the endometrium represents just another, still ill-defined potential role that prolactin plays in the reproductive process.

The prevalence of substance abuse in patients with suspected preterm labor

Judith A. Ney, MD, Sharon L. Dooley, MD, Louis G. Keith, MD, Ira J. Chasnoff, MD, and Michael L. Socol, MD

Chicago, Illinois

Premature labor is a recognized complication of substance abuse in pregnancy. However, the prevalence of substance abuse in patients first seen with symptoms of preterm labor and who deny use of illicit drugs is unknown. Between July 1, 1988, and December 15, 1988, 141 patients first seen at Northwestern Memorial Hospital in suspected preterm labor and a comparison group of 108 uncomplicated laboring term patients had urine toxicology screening performed to detect substance abuse. Positive urine toxicology screenings were found in 24 of 141 (17.0%) patients with suspected preterm labor and in 3 of 108 (2.8%) patients in the comparison group. The most common substance identified was cocaine (14/24 and 1/3, respectively). Of those patients in suspected preterm labor, 22 of 86 (25.6%) clinic patients had positive urine toxicology screenings as did 2 of 55 (3.6%) private patients. On the basis of our observations, we recommend that patients admitted in possible preterm labor be encouraged to submit to screening for substance abuse so that appropriate counseling and prenatal and neonatal care become available for these high-risk patients. (Am J Obstet Gynecol 1990;162:1562-7.)

Key words: Premature labor, substance abuse, cocaine

The neonatal complications of prematurity are responsible for the majority of adverse perinatal outcomes. Fuchs[1] reported that 8% of preterm births accounted for 75% of perinatal deaths, and it has been estimated that up to three fourths of mental and physical handicaps are directly linked to preterm birth.[2] Despite the aggressive use of tocolytic agents over the past decade, the incidence of preterm delivery has not decreased but remains at 7% to 10%.[3-5] Furthermore, whereas programs aimed at preterm birth prevention such as those advocated by Papiernik[6] and Creasy[7] have been reported to be beneficial, experience with such programs has not been uniformly successful.

Substance abuse is a recognized risk factor for preterm delivery.[5, 9] However, the prevalence of substance abuse in patients first seen with symptoms of preterm labor and who deny substance abuse is unknown. The present study was undertaken to determine the magnitude of this problem at our institution, a tertiary center within a large urban area.

Material and methods

The study population comprised 141 patients first seen at Northwestern Memorial Hospital between July 1, 1988, and December 15, 1988, in suspected preterm labor (between 22 and 36 weeks' gestation). Patients were excluded if they admitted to substance abuse during the current pregnancy or if they were taking prescription medication that might lead to a falsely positive urine toxicology screening. As part of our routine evaluation of patients suspected to be in preterm labor, a urine specimen was analyzed for the presence of illicit drugs (e.g., marijuana, cocaine, benzodiazepines, opiates, barbiturates, amphetamines, methadone hydrochloride, and phencyclidine hydrochloride) shortly after admission. Positive screens did not affect obstetric decisions on labor and delivery but prompted referral to our comprehensive perinatal clinic for women with substance abuse.[10]

To determine the prevalence of undetected substance abuse in our term population, 108 arbitrarily chosen patients with uncomplicated pregnancies at ≥37 weeks' gestation similarly had urine screenings obtained when in early labor and analyzed for the presence of illicit drugs. These screenings were performed on otherwise discarded urine specimens and testing was performed at no cost to the patient. Demographic data were collected without identifying information so that patient anonymity and confidentiality were maintained.

Patients first seen with regular uterine contractions suggestive of premature labor were initially managed

Table I. Demographic data

	Suspected preterm labor (n = 141)				*Term labor*			
	Clinic (n = 86)		*Private (n = 55)*		*Clinic (n = 39)*		*Private (n = 69)*	
	No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
Maternal age	23.6 ± 5.2	—	30.7 ± 5.8	—	25.1 ± 5.0	—	31.6 ± 5.0	—
Primigravid	19	22	16	29	± 9	23	25	36
Patients with ≥ one living child	53	62	19	35	23	59	30	43

with bed rest and intravenous hydration. Those patients with intact membranes whose contractions ceased were discharged and their activities were restricted. Tocolysis with intravenous magnesium sulfate or ritodrine was initiated in patients with persistent regular uterine contractions at gestational ages of <36 weeks; observation of documented cervical change was encouraged but not required for the diagnosis of preterm labor. Patients with suspected preterm labor complicated by premature rupture of membranes were managed expectantly without an attempt at tocolytic therapy. Hospitalized patients and those discharged with oral β-sympathomimetic agents prescribed underwent follow-up with weekly nonstress tests and serial ultrasonographic examinations for fetal growth. Oral β-sympathomimetic agents were continued until 37 weeks' gestation or until labor ensued.

Statistical analysis of the prevalence of substance abuse and outcome measures was performed with the Student *t* test, the Fisher exact test, and the χ^2 test where appropriate. Significance was assumed at the $p < 0.05$ level.

Results

Demographic data for both the preterm and the term patients are listed in Table I. The results of urine toxicology screenings for both patient groups are shown in Table II. Positive screenings for use of illicit drugs were noted in 24 of 141 (17.0%) preterm and 3 of 108 (2.8%) term patients ($\chi^2 = 12.83$; $p < 0.001$). The most commonly identified substance was cocaine, (14/24 and 1/3, respectively). More than one illicit drug was identified in six patients.

Of those patients in suspected preterm labor, 22 of 86 (25.6%) clinic patients had positive urine toxicology screenings compared with 2 of 55 (3.6%) private patients ($\chi^2 = 9.94$; $p < 0.001$). Six of 58 (10.3%) white patients had positive urine toxicology screenings compared with 18 of 83 (21.7%) nonwhite patients (p, NS).

Table II. Urine toxicology results

	Suspected preterm labor (n = 141)	*Term labor (n = 108)*
Positive screening		
Cocaine	14	1
Cannabinoids	9	1
Opiates	2	0
Other (barbiturates, benzodiazepines, phencyclidine, amphetamines)	6	1
No. of patients with positive screening	24 (17%)*	3 (2.8%)

*More than one illicit drug was identified in six patients.

The demographic distribution of the term comparison group is representative of the obstetric patient population at Northwestern Memorial Hospital. The three (7.7%) positive urine toxicology screenings were identified in the 39 clinic patients; there were no positive urine toxicology screenings in the 69 private patients.

Outcome measures are depicted for the preterm study group in Table III. Within the clinic and private patient subgroups, the identification of illicit drug use was not associated with differences in the mean or distribution of gestational age at delivery, mean birth weight, or incidence of a small-for-gestational-age newborn.[11] There were also no differences in the use of tocolytic drugs or the incidence of premature rupture of membranes.

Comment

The incidence of illicit drug use in our population of patients first seen with symptoms suggestive of preterm labor but who previously did not admit to substance abuse during the index pregnancy was 17% (24/141). This problem was not limited by demo-

Table III. Outcome measures in suspected preterm labor subgroups

	Clinic (n = 86)		*Private (n = 55)*	
	Positive toxicology (n = 22)	*Negative toxicology (n = 64)*	*Positive toxicology (n = 2)*	*Negative toxicology (n = 53)*

Birth weight <10th percentile	2 (9%)	4 (6%)	1 (50%)	5 (9%)

graphic boundaries, although urine toxicology screenings were more often positive in clinic patients than in private patients.

The most common substance identified was cocaine, which has been reported to have a strong association with preterm birth, placental abruption, growth retardation, and possibly with congenital anomalies.[9, 10, 12, 13] Cocaine has a sympathomimetic effect by blocking the reuptake of norepinephrine and dopamine from the postsynaptic neuron. The resultant increased availability of neurotransmitters produces an abrupt peripheral vasoconstriction, tachycardia, and hypertension.[14] In addition, parenterally administered cocaine in the pregnant ewe has been shown to reduce uterine blood flow and increase uterine contractions.[15] Although some investigators have found marijuana to be more commonly abused by pregnant women than cocaine, our data are in keeping with a recent 36-hospital survey. In that report 0.4% to 27% had screenings positive for substance abuse with seven hospitals reporting cocaine abuse in >9%.[16]

Somewhat surprising to us was the observation that patients with positive urine toxicology screenings were subsequently delivered of infants with similar gestational ages and similar birth weights compared with those with negative screenings. We cannot be certain as to the extent identification of use of illicit drugs influenced ultimate outcome but this knowledge may contribute significantly. Indeed, multidisciplinary nonjudgmental interventions aimed at abstinence for the remainder of pregnancy have been shown to improve perinatal outcome.[9, 10]

The 2.8% (3/108) incidence of substance abuse in our comparison group is consistent with reports that suggest use in 1% to 10% of the pregnant population.[16-18] Our frequency of positive intrapartum urine screenings could be construed as low for an urban population, but substance abuse is sporadic and a single negative urine toxicology study underestimates use over an entire pregnancy. It is difficult to obtain an ideal comparison group for patients in suspected preterm labor, and the demographic characteristics of our two groups differ. This likely reflects the known association of prematurity with nonwhite race and low socioeconomic status—factors that may also be associated with the prevalence of the use of illicit drugs.

Although our study does not show a cause-and-effect relationship, we found a high rate of positive urine toxicology screenings in women admitted in suspected preterm labor. Most risk factors associated with premature delivery cannot be altered, but substance abuse is potentially treatable. On the basis of our observations, we recommend that patients admitted with symptoms suggestive of preterm labor be encouraged to submit to screening for substance abuse so that appropriate counseling and prenatal and neonatal care become available for these high-risk patients.

Discussion

DR. ROBERT J. SOKOL, Detroit, Michigan. In this study, Dr. Ney and her colleagues found that positive urine toxicologic screenings for drugs of abuse were sixfold more common in patients without previously known substance abuse who were first seen in suspected preterm labor than in those first seen in labor at term. On this basis, they recommend urine toxicologic screening of preterm labor patients. The most common drug identified was cocaine. Cocaine use in pregnancy has been reported to be associated with increases in spontaneous abortion, stillbirth, low birth weight (both preterm delivery and intrauterine growth retardation), premature rupture of the membranes, abruptio placentae, neonatal behavioral change and possibly congenital anomalies including those of the eyes, skeletal system, and urinary tract.[1] Clearly, the authors have hit on an important subject on which to focus attention.

Although I believe that the observation made by the investigators is sound, there are questions concerning both the methods used in this study and the inferences made from it. First, how were the groups chosen? There is nothing to indicate that the preterm patients studied were a consecutive series or how the control group was actually selected other than the statement that it was arbitrary. Could there be selection bias?

On the basis of the increase in cocaine use detected in patients entering the hospital with symptoms of preterm labor, the authors speculate on a possible physiologic mechanism. Because some risks associated with preterm labor are also associated with cocaine use (e.g., low socioeconomic status and premature rupture of the membranes) their argument could be considerably strengthened by a multivariate analysis to adjust for confounding; unfortunately they did not perform one.

To attempt to isolate any impact of cocaine on preterm labor, we submitted data from a sample of 3316 consecutive patients who entered a prospective study of perinatal drug and alcohol abuse to discriminant analysis. We contrasted preterm births with nonpreterm births for maternal characteristics, cigarette smoking, and drug and alcohol abuse. In light of types of substance use in isolation, preterm delivery was associated with heavier smoking, higher alcohol intake, and greater likelihood of cocaine and opiate abuse, as in the study under discussion. However, when the risks are considered jointly the only significant difference in substance use between our groups was that the mothers who were delivered of preterm infants were more likely to use narcotics. There was no difference in cocaine use. This does not support the investigators' speculation that pharmacologically linked cocaine and threatened preterm labor. However, the authors evaluated drug use just before admission, whereas in the Detroit data, drug use was documented throughout pregnancy but not specifically on admission for labor. Thus, cocaine use might act as an acute trigger for uterine contractions—the multivariate analysis presented here does not rule out this possibility, but the small series presented by the authors does not have adequate power to detect differences that might support the possibility. Further studies in human pregnancy are needed.

Finally, what about the authors' recommendation for urine toxicology for patients first seen in preterm labor? To evaluate this recommendation one has to make some suppositions. Given that urine toxicologies for drugs of abuse could be obtained for $25 each, and given the prevalence of positive results in the study for staff patients of 26%, it would cost just <$100 to detect each substance abuser on a staff service. But among private patients with a much lower prevalence of substance abuse (<4%), the cost per ascertained case rises to almost $700. The situation is worsened by the insensitivity of a single urine screening.[2] It is likely to miss perhaps one half to two thirds of patients who abuse drugs. Also, detection when the patient is already in premature labor is too late to prevent most of the adverse perinatal consequences of cocaine. Detection early in pregnancy could facilitate focussed prevention. Thus, a more cost-effective approach might be to begin screening early in pregnancy, but only for populations with a high prevalence of substance abuse or possibly for patients who have other factors associated with substance abuse, such as low socioeconomic status or cigarette smoking.[3] I would be interested in the authors' views on this approach.

Even with the caveats raised in these comments, I reemphasize the importance of this finding. In a series of >3000 patients so far unreported from our service at Hutzel Hospital in Detroit, Dr. Enrique Ostrea, chief of Neonatology, has performed toxicologic screenings on meconium—a method at least two to three times more sensitive than isolated urine screenings in the detection of perinatal substance abuse. A total of 42% of all deliveries showed at least one drug; 20% of the meconium samples showed evidence of cocaine use during pregnancy (Enrique M. Ostrea, Jr., MD, personal communication). This is truly a problem of epidemic proportions, one of which as obstetricians we must be acutely aware.

DR. VIRGINIA R. LUPO, Minneapolis, Minnesota. The problem of substance abuse in pregnancy is still taboo in many prenatal clinics and labor and delivery suites throughout the country. Physicians trained more than 3 or 4 years ago have probably never managed a patient with a crack-induced abruption or seen a child with a porencephalic cyst as a result of an anoxic cerebral intrauterine insult. The relationship of cocaine to precipitate delivery at any gestational age was only described in 1983 by David Acker at Boston City Hospital,[1] and even now the contribution of this drug to preterm labor and delivery is not acknowledged in the day-to-day workings of many obstetricians. The thought "my patient cannot have this problem" still prevails. The importance of Dr. Ney's study lies in confronting us with the prevalence of drug abuse among women in preterm labor in a mixed public-private suburban hospital and compels us to look for similar substance abuse among our own patients.

I do have several questions about this well-designed and much needed study.

Did your institutional review board require informed patient consent before participation in this study? If so, did some potential study participants refuse and do you think this in any way biased your results such that an underreporting of substance abuse occurred?

Was the widespread use of cocaine relative to the cannabinoids expected? Did any pattern of combined substance abuse arise? I am constantly surprised by the varying patterns of substance abuse observed throughout the country. Because the excretion of cannabinoids can last up to 2 to 3 weeks, the 6% prevalence reflects the use in the past several weeks before admission. However, the cocaine assay reflects drug use only in the past 48 hours because of the rapid metabolism of this compound. In some respects the cannabinoid assay could be said to detect prevalence and the cocaine assay could be said to detect incidence. It is somewhat unusual to see more use of cocaine than of cannabinoids in the general population. Recently I completed a survey of patients at nine different labor and delivery suites in the Minneapolis—St. Paul area, searching for use of controlled substances among 1800 women. I realize that the inclusion of opiates and barbiturates can be confusing in statistical results, inasmuch as many of these drugs may be used on a prescription basis. Even if cocaine and cannabinoid use only was reported in Dr. Ney's study though, a prevalence of 16% of urine tests would be seen. In my study, cannabinoid use exceeded cocaine use in the public, private, and mixed public-private hospital.

I am curious as to whether a pattern was seen in which cocaine was selectively associated with cannabinoid use, or did cannabinoids function as a marker for abuse of other substances?

Does the subset of preterm labor patients who use cocaine deliver earlier than the nonusing population? The observation that women with positive drug screens were delivered of infants no earlier on average than women with negative screenings leads me to question the subcategories of specific drug use. Because we have little reason to suspect cannabinoid use as a cause of preterm labor and delivery, I am curious as to whether the cocaine-abusing patients were delivered of infants earlier than women negative for substance abuse.

Finally I would like to comment on the issue of drug screening in pregnancy. Cocaine is a large cause of preventable abnormal neonatal outcome. The ability of this drug to destroy family integrity because of drug-seeking behavior is a national tragedy. In Minnesota we have a law that mandates any physician who suspects a pregnant women of drug abuse to perform a urine toxicology screening and if results are positive the physician is mandated to report this to the local child protection services, which consider such use as neglect. Provision for the implementation of civil commitment proceedings for drug treatment is also present within this law. Our state has several residential drug treatment centers tailored to the needs of pregnant women, and some provide for these women to keep their other children with them while in treatment. The physicians of our state strongly believe that this law will help protect the mose defenseless new members of our society while not criminalizing the behavior of their mothers. The law may dissuade some women from seeking prenatal care but it is a much more sympathetic approach than that currently debated in the California legislature, which proposes mandatory 3-year imprisonment for women found to be abusing drugs during pregnancy.

Substance abuse, especially cocaine abuse but also abuse of legal drugs such as alcohol and nicotine, is a problem that will not go away by ignoring it. If it has

not spread to every private, every rural, and every hometown hospital in this country, wait a couple of weeks; it is coming. Studies such as Dr. Ney's underscore its extent. It is for us as physicians to be right out in front as the media and the legislatures try to assess, judge, and punish the users. Our first and only mission as physicians is to heal. This must be done by relentless diagnosis of the disease of drug abuse, by treatment of the disease, and by protection of the children from the rampages of the disease.

REFERENCE

1. Acker D, Sachs BP, Tracey KJ, Wise WE. Abruptio placentae associated with cocaine use. AM J OBSTET GYNECOL 1983;146:220.

DR. ROBERT GOODLIN, Denver, Colorado. In the Denver General Hospital the use of cocaine appears to have increased roughly 300% to 400% in the past few years, but our incidence of premature labor has actually gone down.

DR. EDUARD EICHNER, Cleveland, Ohio. I just want to go back a few generations. Back in the late 1920s and early 1930s we used cocaine to stop nausea and vomiting in pregnancy. We did not get toxicity, and we stopped it soon enough; the patients cooperated with us actually. There was no problem there. That was at the time when cocaine had become a local anesthetic for tonsillectomies.

At about the same time, The Upjohn Company took morphine out of their cough syrup because of the drug law and replaced it with heroin. Within a couple years we were involved with marked toxicity and heroin drug habit formation, so much so that in the middle 1930s Upjohn took heroin out and replaced it with codeine.

The only other thing along that same line is the start of prohibition at the time. We as physicians were given permission to write alcohol prescriptions for our patients if we deemed it necessary. Unfortunately, we never got the data as to whether it was good, bad, or indifferent; but I thought I would let you know.

DR. NEY (Closing). I will comment first about the possible selection bias of our study groups. We attempted to screen sequential patients first seen with symptoms of preterm labor. Patients who were first seen on the labor and delivery suite with contractions at <37 weeks' gestation were screened per protocol. These patients were not necessarily delivered of preterm infants but did come to the hospital with contractions. It is true that you do not always screen every patient who meets criteria, but we did make that attempt. As for our term group, we also attempted to get sequential patients during a 2-month period.

We were looking not only at the prevalence of unsuspected substance abuse, but also at whether there is a link between substance abuse and preterm contractions before preterm delivery. Our belief is that once preterm delivery occurs, it is too late. We wanted to determine whether we could effect a decrease in premature delivery in detection of abuse and referral of these patients to special intervention programs.

I agree with Dr. Sokol that we need to do further study and that we did not distinguish the contributions of cigarettes and alcohol in these subgroups.

I appreciate Dr. Sokol's cost analysis. He clearly shows benefit for our clinic population. I do not think that $700 is too much to pay to detect a substance abusing private patient who is in premature labor, who has not yet been delivered of infants, and whose pregnancy outcome we may improve.

In reference to Dr. Lupo's comment about patient consent and the possible loss of some patients, in Illinois, Minnesota, and quite a few other states when a urine toxicology is indicated as part of a medical evaluation, patient consent is not required. Our patients were informed that the urine toxicology was to be done as part of our evaluation of preterm labor, but consent was not solicited.

Dr. Lupo has found, as have other researchers in this field, that marijuana, not cocaine, is the most common drug of abuse. I think this reflects our study design. We excluded patients who admitted to drug abuse during the index pregnancy because our purpose was to detect the rate of unsuspected substance abuse. Marijuana may be a more common admitted drug of abuse in the general population. Because our entrance criterion was suspected premature labor and cocaine has been implicated to cause uterine contractions, we may have selected for cocaine. I agree that we have not shown cocaine to be more common than marijuana, simply that it appeared more often in this study because of the reasons stated.

We are asked by Dr. Lupo to reanalyze our data and separate cocaine from other substances of abuse. The small numbers involved preclude meaningful conclusions with the data so divided, but I agree that a larger series should be so analyzed. For purposes of description, of the 14 patients who tested positive for cocaine with preterm contractions, 10 (71%) were delivered of infants at <37 weeks' gestation; of the 10 patients who abused only substances other than cocaine, 5 (50%) were delivered of preterm infants; and 71 of the 117 (61%) patients with negative urine screenings were delivered of preterm infants.

Selective termination: Clinical experience and residual risks

Mark I. Evans, MD,[a] Marlene May, RDMS,[a] Arie Drugan, MD,[a] John C. Fletcher, PhD,[b] Mark P. Johnson, MD,[a] and Robert J. Sokol, MD[a]

Detroit, Michigan, and Charlottesville, Virginia

Assisted reproductive technologies have aided thousands of couples, but complications have resulted in multifetal pregnancies creating a bitter irony for infertility patients. In an effort to increase the rate of intact survival, we have successfully performed transabdominal first-trimester selective termination procedures on 22 pregnancies including one octuplet, five quintuplet, twelve quadruplet, and four triplet gestations. There have been eight sets of twins, and two singletons delivered, seven twin pregnancies are ongoing, and one early and four late losses of pregnancies. With experience we now counsel as to a high likelihood of a technically successful procedure, but we still have concerns for late losses. We have tried to balance the arguments about the direct harms of performing selective termination and the obstetric risks of not performing selective termination. We believe that selective termination should not be considered a "social" procedure. Our data do not yet make clear whether one, two, or three is the optimal number of embryos to leave. Therefore, on the basis of both current obstetric risk factors and ethical reasoning we will continue to support our protocol of optimally leaving twins. (Am J Obstet Gynecol 1990;162:1568-75.)

Key words: Selective termination, multifetal pregnancy, fertility drugs

Multiple gestation is a high-risk situation associated with marked increases in maternal complications, perinatal mortality, and morbidity.[1] These risks appear directly proportional to the number of fetuses. The average length of gestation has been estimated to be 35 weeks for twins, 33 weeks for triplets, and 29 weeks for quadruplets.[2] The spontaneous occurrence of multiple pregnancy with three or more fetuses is unavoidable and rare, (1:8100 births for triplets, 1:729,000 births for quadruplets). It is a more frequent sequelae of ovulation induction or in association with assisted reproduction technologies such as gamete intrafallopian transfer (GIFT) or in vitro fertilization (IVF). The incidence of multiple gestation after ovulation induction ranges from 6% to 8% with clomiphene citrate to 15% to 53% with gonadotropins.[3]

Although advances in prenatal care and intensive neonatal care have reduced the mortality and, to a lesser extent, the morbidity of prematurity, the obstetric outcome for triplets or higher number of fetuses is significantly worse than for singleton or even twin pregnancies.[4, 5] The ability to carry quadruplets or more is by any reasonable definition, significantly compromised.

Complications from the use of powerful fertility drugs such as human menopausal gonadotropin (Pergonal preparation of menotropins) or newer agents such as urofollitropin (Metrodin, follicle stimulating hormone preparation) have thus created one of the ultimate ironies in medical care. Usually reserved as the last resort for couples with very significant infertility problems, the use of such drugs has led to situations in which previously infertile women may bear more fetuses than they can safely carry to viability. Spectacular reports both in the medical literature and in the lay media have detailed successes such as the Dionne quintuplets of the 1930s, but also equally infamous tragedies such as the Frustaci septuplets of California in 1985. Whereas the successes have touched the public's heart, the reality is the tragedy of prematurity with associated high risk of fetal death, and significant impairments for survivors have more generally been the rule.[4]

When faced with such potentially tragic circumstances, couples have had to choose among several unpleasant options. Termination of the entire pregnancy with the intent to conceive again is one option. However, because most of these patients are treated for infertility and another conception is not guaranteed, this option has generally been considered unacceptable. A second option is to continue with all the fetuses. In cases of quadruplets or even quintuplets, survival of some or all is certainly possible, but there is significant risk of long-term morbidity. With six or more fetuses

the chance of survival is extremely low, and in the case of octuplets, the chance is essentially zero.

A third option is selective termination, which over the course of the past few years has become an accepted option when faced with the potential perinatal tragedy associated with multiple fetuses.[6-9] We report here our experiences with 22 such procedures over a 3-year period, from both the scientific perspective and the ethical and public debates that have evolved.

Material and methods

During a 3-year period (January 1986 through April 1989) we counseled 25 couples who had multifetal pregnancies as a result of treatment of infertility. Of 22 couples who came to our program for counseling and selective termination, three were from the Detroit metropolitan area; the remainder were referred from many areas of the country. Of these 22 couples, 17 had no children, three had one child, one had two children, and one had three children. Twelve pregnancies had been achieved through gonadotropin induction, six through GIFT, and four through IVF.

The approach to counseling for selective termination has continually evolved over the 3-year period. Originally our counseling emphasized the dearth of reliable information about the outcome of multifetal pregnancies, recognized that most reports in the lay media were heavily biased toward either spectacular successes or tragedies, and was particularly deficient with regard to information on early pregnancy losses. Further, we knew that much of the available data were anecdotal. Initially we also did not know what the chances would be of successfully performing the procedure. We did not know what the risk of long-term complications might be during both the remainder of the pregnancy and postnatally. We emphasized that the procedure could result in the loss of the entire pregnancy and that the exact risks were unknown. Our present counseling has evolved to include an essentially 100% chance of technically performing the procedure, but continues to stress the uncertainty as to long-term complications and potential risks from the procedure.

For selective termination we used ultrasonographic equipment (GE3600, General Electric, Denver) equipped with a 3.5 and 5.0 MHz linear array transducer. A "free hand" technique of needle guidance was used in all cases.

For the first two patients, one woman with quadruplets and one with octuplets, the procedures were performed transabdominally by repeated needle punctures of the embryonic thorax to produce mechanical disruption of the fetus. All the remaining cases have been done by intrathoracic injection with a 22 gauge needle of approximately 0.5 ml of potassium chloride solution (2 mEq/ml) (Fig. 1). The duration of the procedure per embryo has varied from 3 minutes to 1 hour. Because we learned that a sharp angling of the needle through the skin is more painful to the mother than a direct, downward, vertical approach, in nearly all cases a separate transabdominal needle entry has been made for each embryo.

Results

In five of the 22 patients, the number of embryos we found on ultrasonography was different from expectations on the basis of the presenting history. In three patients we found fewer and in two others we found more than the number expected.

In 21 of the 22 pregnancies, with our encouragement the couples elected to reduce the number to twins, regardless of the starting number of fetuses (Table I). One woman with quadruplets wished to be reduced only to triplets. One woman asked to go to a singleton pregnancy. However, we believed we could not fulfill that request; we have detailed our ethical reasoning previously.[6]

All 22 attempted procedures were performed successfully, reducing the number of embryos to the desired number. All were done at one sitting except for the octuplet pregnancy that was deliberately performed in two sessions separated by 1 week. The majority of the procedures were done at 10 or 11 weeks' gestation (Table II).

Five patients lost the entire pregnancy after selective termination. Approximately 1 week after an apparently uneventful procedure, one woman suffered a spontaneous abortion of the remaining two embryos. Four other women lost their twins later in gestation (Table II). Of these, in one case one of the remaining twins had Potter sequence, although scans at 1 and 3 weeks after the procedure had been normal. She suffered rupture of membranes at 20 weeks' gestation and lost the twins. In a second case, rupture of membranes followed genetic amniocentesis performed by a highly qualified physician. In the remaining cases premature labor and spontaneous rupture of membranes occurred, respectively. In two other patients one of the remaining twins was lost—one at 1 week after the procedure and the other after a genetic amniocentesis. Normal singleton pregnancies continued. Fifteen twin pregnancies have been delivered—13 at >35 weeks' gestation, one at 28 weeks' gestation, one at 31 weeks' gestation, and two singletons near term. All have been appropriate for gestational age with no obvious congenital abnormalities.

Comment

Clinical issues. Our experiences over the past 3 years and those of a few other groups around the world[7-13] have shown that selective termination can be success-

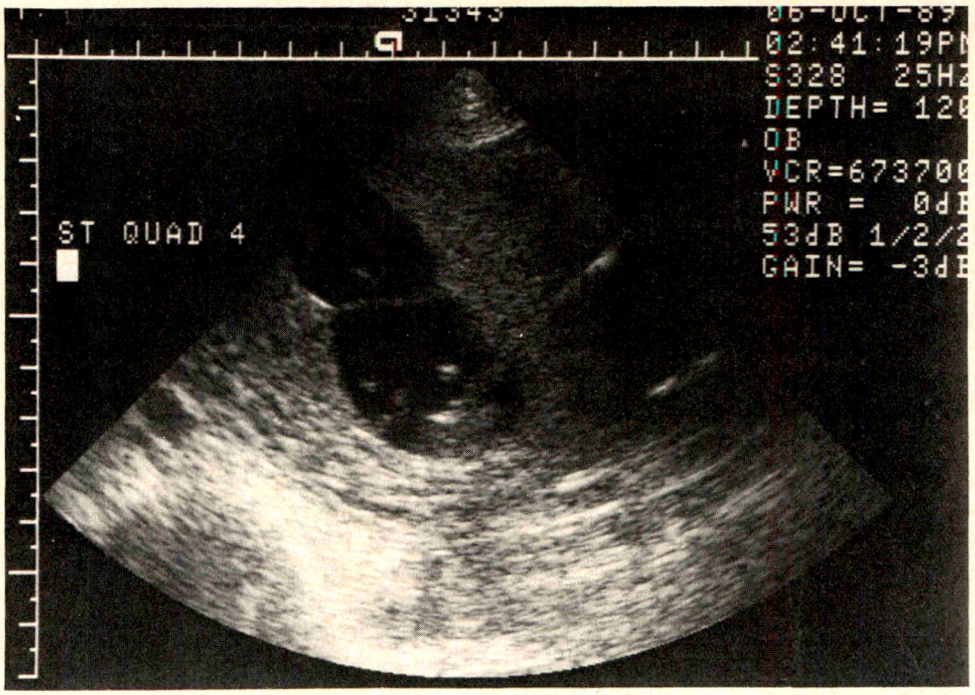

Fig. 1. Ultrasonically guided entry of 22 gauge needle into embryonic thorax.

fully accomplished, and for the majority of patients live born twins will be born. Our pregnancy loss rate (5/22 or 22.7%) is lower than the 35.4% (4/11) reported by Berkowitz et al.[7] and higher than the 11.9% (5/42) reported by Salat-Baroux et al.[10] However, Salat-Baroux mentions only immediate complications (post-procedure infections) leading to pregnancy loss. Immediate pregnancy losses (within 1 week after the procedure) occurred in one case each in ours and in Berkowitz's[7] series and were associated with vaginal bleeding. Late rupture of membranes was not reported in Salat-Baroux's study,[10] but has affected patients in both Berkowitz's and our series. Dumez and Oury[8] originally used a transcervical suction method, but abandoned it after experiencing an approximately 40% loss rate. We have concerns that the transcervical aspiration of the lower sacs in the uterus, as used by Salat-Baroux,[10] may cause devitalization of the membranes over the internal os. Such devitalization could create a potential nidus for ascending infection that may predispose the patient to premature membrane rupture several weeks later.[7] However, we have seen ruptured membranes even when the transabdominal approach was used exclusively and the lower gestational sacs were avoided.

Questions remain concerning the risk/benefit ratio of selective termination and are based in part on the fact that information on the natural history of multifetal pregnancies is still very incomplete. We have collected such data and have found that there are considerable discrepancies between the experiences reported by perinatologists, who often deal with what we believe is a biased sample, as compared with those reported by reproductive endocrinologists, who can more fully document early fetal loss.

The best time to perform the procedure is in part dependent on the method used to achieve reduction of fetal number. Advocates of the transcervical or transvaginal suction approach generally tend to perform the procedure earlier, between 6 to 9 weeks' gestation. In our patients, with the use of a transabdominal approach most procedures were done at 10 to 11 weeks' gestation. Although performance of the procedure as early as 6 to 7 weeks' gestation is feasible, at this age there still seems to be a considerable risk for the spontaneous loss of embryos. For example, with ultrasonographic documentation of viable twins in early pregnancy, a 21.2% incidence of "vanishing twins" has been reported.[14] Three of our patients had spontaneous loss of fetal heart activity between initial diagnosis and procedure (generally a 3 to 5 week period), although we cannot exclude simple misdiagnosis of fetal number. If the procedure is done relatively early in gestation (before 8 gestational weeks), there would still be concern about the possibility of ending up without viable fetuses even when one or two were intentionally left intact. With the transabdominal approach, procedures at 9 to 11 weeks' gestation have seemed technically easier and our original concerns[6] about disseminated intravascular coagulation (as related to a larger mass of fetal tissue left

in utero) have not been borne out. Thus, we recommend a transabdominal approach at 9 to 11 weeks' gestation for selective termination procedures.

We have suggested, for both clinical and ethical reasons that reduction of the number of fetuses to twins was most appropriate. Further clinical evaluation of our data will be required before the optimal number of living embryos, whether it be one, two, or three can be determined. Because selective termination is not a "social" procedure and on the basis of our belief that there is currently no medical or ethical justification for reduction to fewer than twins, we have turned down requests to reduce one normal twin or to reduce triplets or more to a singleton pregnancy. The obstetric complications and outcome of twins are somewhat worse than that of singleton pregnancies.[1-3] However, twins leave some margin for error in the event something happens to one of the remaining twins as has been seen in our series. Furthermore, these patients are essentially all infertility couples for whom two children may satisfy their family planning desires. The reported lower loss rate by Salat-Baroux[10] may be a function of both lower average starting numbers and perhaps lower stopping number. The issue of whether there is better perinatal outcome of singletons versus twins will require a much larger data set and must be factored by the starting number and other confounding variables.

With the current protocol there continues to be a high loss rate. To date it is not clear how to interpret the data as to which cases may have been procedure related, the technical issues of a learning curve, and whether overall better perinatal outcome might not be achieved by aiming for singleton pregnancies. If so, we will have to rethink out ethical arguments.

Ethical and political issues. We have previously reported in great detail an ethical justification for our first attempts to offer selective termination and for choosing *selective termination* as the term for this procedure.[6] Public opinion and the media in general have accepted the concept that the first-trimester embryo is not yet a viable person and therefore is endowed less protection under the law than that of a child. This allows the concept of selective termination to remain within the realm of ethical standards acceptable to the general populous, whereas the concept of selective infanticide would never be considered acceptable within the same standards.

Whereas we have not been surprised by the negative response of antiabortion groups, we have been pleased by the general acceptance of the view that the ethics of selective termination are very different from the ethics of abortion per se. Despite the inherent controversy that surrounds any technology that involves abortion, we have received only one "hate" letter written in crayon and have had begrudging acceptance even from very conservative quarters. One of us (M. I. E.) has been attacked by the editor of a support group for triplets who declared in the *Triplet Connection* that she was "horrified recently to learn of a fertility specialist in Detroit who performs selective abortions on all patients with more than two infants" demonstrating clearly that they had not read our original article.[6] None of us is an endocrinologist, nor do we do infertility work. The *Triplet Connection* contends that the outcomes in multifetal pregnancies are good and therefore selective termination should hardly ever be needed, and if done should reduce the number of embryos to three or even four. Our survey of their data is less optimistic than their conclusion. However, we certainly agree that everyone's data are significantly flawed, and all interpretations are tenuous.

The introduction of techniques such as embryo cryopreservation may help to reduce the risk of multifetal pregnancy associated with replacement of multiple embryos in IVF or GIFT. It seems that the relatively few cases of multifetal pregnancies that result from treatment, despite the approximately 20,000 patients per year in this country who are treated with gonadotropins, must be considered a major success rather than a tragedy. We believe that selective termination is a small price to pay for the thousands of babies made possible for childless couples. However, we do believe that selective termination should not be viewed as an end, but only as an interim step until improvements in infertility treatment alleviate the need for its use.

Table I. Selective termination procedures

No. of pregnancies	*First seen with*	*Reduced to*
1	Octuplets	Twins
5	Quintuplets	Twins
12	Quadruplets	11 twins, 1 triplet
4	Triplets	Twins

Table II. Timing and outcome of selective termination

Gestation (wk)	8	9	10	11	12
No. of procedures	1	2	12	6	1
Pregnancy losses	0	0	2*	3†	0

*Case 3, one fetus with Potter sequence, spontaneous rupture of membranes at 20 weeks' gestation. Case 4, premature onset of labor at 18 weeks' gestation.

†Case 9, spontaneous rupture of membranes after genetic amniocentesis at 17 weeks' gestation. Case 10, vaginal bleeding for 1 week with subsequent loss at 12 weeks' gestation. Case 15, spontaneous rupture of membranes 7 weeks after procedure.

In summary, we believe that selective termination has been shown to be a contribution in the treatment of the tragic circumstances of a multifetal pregnancy. However, we do not yet have the data base to know definitely at what number of embryos selective termination should first be offered or what number of embryos should optimally be left. Until better data are available we will continue the current protocol on the basis of our present experience of offering selective termination to multiple gestations of three or more with reduction of embryo number to twins.

Discussion

Dr. Marilynn C. Frederiksen, Chicago, Illinois. Dr. Mark Evans and his colleagues have presented their clinical experience in the performance of selective fetal termination in patients with multiple-gestation pregnancies as a result of ovulation induction. In their previous article they took the position on a principled ethical basis that they could not support the performance of selective fetal termination for purely social reasons.[1] However, with the use of a utilitarian (risk/benefit) argument they could justify selective termination in grand multiple-gestation pregnancies because without such a procedure all fetuses would be lost or suffer significant perinatal morbidity. They further argued, again with the use of a pure risk/benefit analysis, that reduction of fetal number to twins was optimal. This in essence is the hypothesis that this second article is testing. They report from their experience that selective termination is technically feasible. They report an overall pregnancy loss rate of 22.7%, of which only a small portion (1 loss from 22 procedures) can be procedurally related. It remains to be proved whether the remaining pregnancy losses are procedurally related or related to the decision to reduce these multiple-gestation pregnancies to no lower than twin gestations.

Of comparative interest Salat-Baroux et al.[2] described in a 1988 article a somewhat different transcervical procedure to reduce multiple-gestation pregnancies. His clinical series reported the pregnancy outcome of 42 multiple-gestation pregnancies that were selectively reduced. The overall pregnancy loss rate was only 11%, thought to be directly related to the procedure. In the remaining 37 pregnancies, selective reduction resulted in 62% singleton gestations and 38% twin gestations with no reported late losses. His procedure and subsequent pregnancy management cannot be directly compared with that described by Dr. Evans and most probably has a a higher procedurally related pregnancy loss rate, 5 of 42 versus 1 of 22, respectively. However, his clinical protocol allowed for the majority of patients to carry singleton gestations, and perhaps this accounts for the pregnancy loss rate that was half that reported by Dr. Evans.

To assess the fetal loss rate of singleton versus twin pregnancies, we analyzed 6 years of data, comprising some 25,700 births that occurred at ≥20 weeks' gestation, from Memorial Hospital of Northwestern University and found a greater than fourfold higher loss rate in pregnancies with twin gestations as compared with singleton gestations. This should remind us and serve to emphasize that a singleton pregnancy is less likely to result in fetal mortality.

Dr. Evans bases his clinical protocol of reducing multiple gestations to twins on a risk/benefit analysis, but the data presented do not answer whether leaving a twin gestation provides a better outcome than a singleton gestation. If Dr. Evans and his colleagues wish to decrease the overall residual risk, and indeed increase the number of women who take well babies home, then his clinical protocol needs to show that reduction to a

twin gestation offers less risk and more benefit than reduction to a singleton gestation.

2. Salat-Baroux J, Aknin J, Antoine JM, Alamowitch R. The management of multiple pregnancies after induction for superovulation. Hum Reprod 1988;3:399-401.

Dr. Frank H. Boehm, Nashville, Tennessee. The article by Dr. Evans and his colleagues contains important information for those of us who administer health care to women because of several factors. First, the 22-patient sample size provides considerable experience and information that can be used in counseling patients who are candidates for such a procedure. Second, the ethical discussion, whereas controversial, does stimulate the thinking process on this contemporary issue.

The problem of multifetal pregnancy is not rare. Anovulation and ovulatory disorders are present in approximately 20% of infertile couples, and ovulation is achievable in >90% of these women with approximately 1% to 2% resulting in a greater number of conceptuses than twins.[1] Thus many of us will face the problem of properly counseling patients at some stage on the subject of selective termination.

Evans and his group have presented 22 patients who underwent selective termination. These patients had several initial options including aborting all pregnancies, which would result in no live births. At the other extreme, among the 22 patients there were 93 potential live births if intervention was refused after the patients were told of a multifetal pregnancy. With today's technology in perinatal and neonatal medicine, however, these two extremes seem less than ideal. With the assumption that selective termination is not offered, we know that morbidity and mortality of multifetal pregnancies is considerable. Even in the more hopeful situation of triplet gestation, a recent review of 238 cases revealed a 20.3% perinatal mortality rate and a high morbidity rate.[2] Another option that would not involve selective termination involves offering and performing abortion on the six patients with quintuplets and octuplets. This would have resulted in 60 potential live births among the 22 patients. Abortion could of course be offered to the 18 women with quadruplets or more, resulting in only 12 potential live births.

However, if selective termination is offered, as was the case in this report, the number of potential births depends on the number of fetuses left intact. Termination to a singleton gestation would result in 22 potential live births, whereas termination to twins in this group of 22 patients would result in 44 potential live births and termination to triplets would result in 66 potential live births. By promoting termination to twin gestation, Evans and his colleagues achieved 32 potential live births and lost a total of 12 fetuses in 7 patients.

Therefore, we must ask ourselves which of the options are we most comfortable with, and which of the options do we present to our patients? I maintain that all options should be offered to our patients, and that we do so before the process of ovulation induction. It is only in this pretreatment phase that a couple can be properly counseled as to the options they face, and may decide not to attempt medical induction of ovulation because of the potential ethical concerns and dilemmas should a multifetal pregnancy occur. An American College of Obstetricians and Gynecologists' publication[1] states that the process of ovulation should be explained to patients and that potential complications and risks for both mother and fetus, as well as the chances of success, should be outlined. Although not specifically mentioned, selective termination, because it involves abortion, should be discussed in the preovulation induction counseling session. Waiting until a multifetal pregnancy has already occurred in a patient who has strong feelings against abortion and then sustains a poor outcome could result in a charge of wrongful life or birth.

The authors state that they do not know at what number of embryos selective termination should be offered or what number of embryos should optimally be left. I do not believe this is the physician's decision. It is the patient who must decide after having been told the necessary facts and risks for both multifetal pregnancies and selective termination. If physicians have trouble deciding what to offer patients because of the complexities and variables, is it any wonder that our patients may be troubled?

With this article and several others in the literature we are beginning to develop a data base by which to properly counsel our patients. However, this counseling should take place before induction of ovulation so that those patients who do present themselves as candidates for selective termination will have had optimal time to thoroughly discuss and contemplate the several options that are available to them.

2. Petrikovsky BM, Vintzileos AM. Management and outcome of multiple pregnancy of high fetal order: literature review. Obstet Gynecol Surv 1989;44:578-84.

Dr. Maurice J. Mueller, Crescent Springs, Kentucky. Dr. Evans has recently proposed the establishment of an international registry of these multiple pregnancies, and I believe this will give us the information to more effectively counsel these patients.

The review article that Dr. Boehm mentioned was in August 1989 *Obstetrical and Gynecological Survey* by Petrikovsky and Vintzileos. They classified these multiple pregnancies of high fetal order into different numeric classifications such as triplets and quadruplets. The article of Petrikovsky and Vintzileos can be used in coun-

seling patients. There are support groups that can help these parents; in California there is the Triplet Connection and New Jersey has Mothers of Multiples. These can be used for preconceptual counseling.

Dr. Robert M. Rebar, Cincinnati, Ohio. I feel compelled to make a couple of comments. I think everyone in the room would agree that Dr. Evans and the discussants raised important issues in this matter. Clearly we are at a window in time when we have the opportunity to offer our patients technologic advances that do not always result in optimal outcomes. I think the most important statement that Dr. Evans may have made was that selective termination should not be viewed as an end but rather should be reviewed as something that is with us for the present and hopefully will change in the future.

I should think that with the advances in reproductive medicine there will come a time when we will talk about frozen oocytes and frozen embryos and be done with the problems that result from these multiple pregnancies.

In addition, it is interesting to me that in the use of menopausal gonadotropins personally for >15 years, we have not yet achieved anything more than a twin gestation; and that is even before the use of the ultrasonographic technologies that now exist. I think we have known for many years that the use of human menopausal gonadotropin in women who ovulate normally has a clearly increased propensity to result in multiple ovulations and lead to these tragic outcomes that involve more than triplet gestations. I think that the reason we are seeing an increase in some of these multiple gestations derives from the inappropriate use of these agents in a number of cases.

To be sure, we will see these multiple pregnancies in some of the newer technologic procedures such as IVf and GIFT, but there really should not be any reason to see more than three fetuses when human menopausal gonadotropins are used.

I was surprised that Dr. Evans did not discuss the psychologic impact of the procedure on the patients involved. I have been involved with multiple pregnancies that resulted from GIFT with only one couple who considered this alternative. Watching that couple wrestle with the possible choices even with assistance was clearly a very enlightening experience for me and a difficult experience for them.

Last, I think that the statements made by Dr. Boehm are also quite important: that is, to discuss the risks of therapy before the institution of ovulation induction. However, I would remind everyone in this room—and we all are aware of it—that how we present the risks and the benefits of a given procedure clearly also determines the choices that the patients make in our offices. It is possible for different physicians to present the same data to the same patients and have the patients arrive at different decisions merely on the basis of the way of the data are presented to them.

These are difficult issues. They are not issues that will be resolved here, and they are certainly ones that merit our discussion as well as discussions by lay persons.

Dr. Robert J. Blaskiewicz, St. Louis, Missouri. I have two questions for Dr. Evans. One is, who did the counseling? The second is, what is the perinatal mortality rate at your institution for quadruplets and triplets.

Dr. Evans (Closing). From Dr. Frederiksen's remarks, we completely agree that the choice of stopping at twins initially was made on the basis of a utilitarian approach in large measure. I think one fundamental concept that we all have to recognize is that ethics do evolve with technology. I think it is possible that as the perinatal morbidity and mortality of triplets gets better over the next 10 to 15 years, that the point at which the risk/benefit ratio to most people seems to be acceptable might move up. Some people may think it is one now. Some people may think it is two. Some people now also think it is three or even four. I think you may see the number move up as the outcome of triplets and quadruplets improves.

Since these 22 cases were reported, in the past 6 months we have actually performed the procedure for another 14 cases, of which we have had only one loss early in pregnancy and one loss later, suggesting to some degree that the twins outcome may be somewhat better.

As Dr. Mueller said, I am putting together an international registry in which we now have a couple of hundred cases from around the world. I think we are finding that there is still a lot of debate among most centers as to whether one or two is the optimal number of fetuses at this point.

I do agree completely with Dr. Boehm that these issues ought to be discussed preconceptually. Of course, I think it is also quite clear that many patients do not want to hear this kind of information and it does not register even if you spend a lot of time discussing it with them. That is something that needs to be seriously addressed.

It is very clear, as I think we all understand, that some of the cases we have seen should never have happened and probably with better management would not have happened. I think it is also clear that the best infertility specialists with the best of equipment and best of intentions will have this kind of problem occasionally occur. One other philosophic benefit we have seen from our infertility colleagues is there are some patients who are very resistant to gonadotropins. The knowledge that selective termination exists may allow them to be more aggressive in the management of an individual patient, which may mean the difference between getting her to ovulate and to not ovulate. However, the window for getting one or possibly two eggs to ovulate may be very narrow, and there may be a significant overshoot.

I do not have the data to prove it, but I do believe in terms of the specific risks once you have done the procedure are proportional to the starting number.

The study that Dr. Frederiksen mentioned of Salat-Baroux et al. had a higher percentage who started with triplets than we did. To answer Dr. Blaskiewicz's question, of the patients we have counseled, I have counseled all of these patients myself.

We have had essentially none with quadruplets refuse the procedure. We have had about 50% of the patients I have seen with triplets decide to proceed with triplets. This is somewhat biased. Of the now three dozen patients for whom I have performed the procedure, only a few of them have actually come from Michigan. So with the majority of the patients, we have had discussions on the telephone before they fly in to have further in-depth counseling followed by the procedure.

That also obviates the question about what are the perinatal mortality and risks of delivery in our center because of the 36 patients, only one of them has actually had her obstetric care and delivery at Hutzel Hospital. That was a set of quintuplets down to twins, both of whom have done well.

I think, in a pluralistic society, we have to offer our patients all options. However, I think we have to step back from it a little to avoid the issue of merely being technicians to our patients' desires. Whereas some have said that if you are willing to do an abortion of a singleton pregnancy, why would you not be willing to do two to one? I think the issues are very different. Whereas I do not think doing two to one should be made illegal or abortion for sex selection, as has been suggested, should be made illegal, I think that in my personal views that would be unethical. That crosses the line between doing a procedure for a medical indication versus one for a social indication, and I believe I have the right to decline to be involved with that; but I also believe the patient should have the option to pursue that someplace else if so desired.

Although it was not mentioned, I think we have also seen criticisms about how this procedure can be abused such as in sex selection. For example, if a patient who has twins, one boy and one girl, decides she wants to only have a boy or only have a girl, that would be an abuse of the procedure. I have had a couple of patients call to request such and I have declined to be involved.

The data presented by Petrikovsky et al. are very enlightening. However, they still are relatively small. It is hoped that from the registry we are putting together we will be able to have better numbers in a year or so.

Dr. Rebar's comment about the psychologic impact on these patients is very important. All these patients go through a grieving process. The octuplet pregnancy was one of my first two patients for the procedure; and as with many medical procedures, they often start doing something new when you have nothing to lose. It was very clear for the patient with octuplets that there was essentially a zero chance of any survival, let alone with significant morbidity and mortality with an octuplet pregnancy. So that actually made the situation for her relatively easy to reach a conclusion. But still she did wrestle with the loss of the potential other children she might have had. This couple and essentially all the other couples I have seen have felt that this was either the only way or by and large the best way in which they could go home with happy, healthy children.

As far as the support groups, the Triplet Connection for example, what we have found is that if you ever want to see biased counseling, that is where you get it. The Triplet Connection with which I have more experience has lambasted me as the fertility expert in Detroit who aborts all his multiple pregnancies. They never bothered to either call me or even read the article. A, I am not an infertility specialist; and B, that is exactly the opposite of what we have said. They do have a biased population; but even if you take a random sample of one of their publications, it is full of "Our condolences to Mrs. Jones, our condolences to Mrs. Smith."

If you add their own morbidity and mortality, I think it comes out with triplets at around the 20% level that was alluded to early on. I believe that with quadruplets probably the chance of at least one of them having a significant problem is >40%, and it is >50% certainly with quintuplets.

I think the most important point we can have, as Dr. Rebar said, is we must not look at selective termination as an end but only a short-term solution until the point at which our fertility treatments will not give us more embryos than can be safely managed during pregnancy.

Spontaneous cell death in the chorion laeve

Tim H. Parmley, MD

Little Rock, Arkansas

The granulosa cells of the dominant follicle grow, differentiate, and die in a roughly predictable amount of time. Because the simultaneous death of this population of cells results in menstruation, one may say that the life span of this population of cells "times" the menstrual cycle. Metamorphosis in amphibians and morphogenesis in several vertebrates are other examples of developmental milestones that are "timed" by the life span of specific cell populations. In all these examples, cell death is associated with a specific histology, apoptosis. Apoptosis characterizes the cell death that produces the progressive disappearance of the trophoblast in the chorion laeve as term is approached. Therefore, the histology of trophoblastic death in the near-term chorion laeve corresponds to that of populations of cells with life spans that "time" developmental events. The trophoblastic cell population of the chorion laeve is prematurely destroyed by infiltrating maternal leukocytes in cases of chorioamnionitis. (Am J Obstet Gynecol 1990;162:1576-83.)

Key words: Chorion laeve, apoptosis, labor, chorioamnionitis

Individual cells go through cycles in which they are created by division of a precursor, grow and differentiate, and then eventually die. When large numbers of cells do this in a synchronized manner, the result may be the acute loss of an entire tissue. The corpus luteum is an example of such a collection of cells that grow, differentiate, and die in a synchronized manner.[1] Because the simultaneous death of all the hormone-producing cells in the corpus luteum results in menstruation, the life span of the cells of the corpus luteum may be said to measure the length in time of the luteal phase. The timing of many developmental phenomena is apparently controlled by similar collections of cells that synchronously live and die. The timing of some morphogenetic events in vertebrate embryos is achieved in this manner.[2-4] Metamorphosis in amphibians and in insects is similarly "timed."[5, 6]

In each of these examples the life span of the synchronized cells may be prolonged or shortened by other factors such as disease and endogenous hormones. When this alteration occurs the developmental event timed by the life span of the cells is hastened or delayed. An example is that human chorionic gonadotropin (hCG) may prolong the life span of the cells of the corpus luteum and delay endometrial breakdown. For this reason, the synchronized death of the cells is not a primary cause of the developmental event (i.e., morphogenesis, metamorphosis, or menstruation) but only a part of the mechanism that times them. Other factors that control the life span of the cells are more properly termed *primary causes*.

When cell death occurs, in each of these instances it takes the distinctive form of apoptosis. Apoptosis, as opposed to necrosis, is an active energy-requiring process in which single cells die and are removed by phagocytosis without producing an inflammatory reaction.[2] Apoptosis characterizes not only the spontaneous cell death associated with the developmental events mentioned above but many others as well. It appears to be the mechanism of spontaneous cell death in terminally differentiated cells. Glucocorticoids induce differentiation in many cell populations and this may be the mechanism whereby they produce apoptosis.[7] Apoptosis also characterizes tissues that involute when hormone support is withdrawn,[8] such as premenstrual endometrium. Histologically, apoptosis is characterized by condensation, shrinkage, and ultimate fragmentation of nuclei. Cytoplasmic shrinkage and destruction occurs simultaneously, resulting in highly eosinophilic bodies that often contain nuclear fragments. The bodies seem to pull away or shrink from neighboring cells.

Inasmuch as gestation is a reproductive event with a finite length, we asked if a population of synchronized cells could be located with an apparent life span correlated with the length of gestation and with a mode of death characterized by apoptosis. The increasing interest in the fetal membranes as the site at which labor is initiated suggested that such a population might be found in the amnion or chorion laeve.

Material and methods

We selected a 6-month period over which it was institutional policy to send all placentas for pathologic examination. We then reviewed the clinical records from each case in which a placenta had been submitted. A case was selected for study if the clinical estimate of

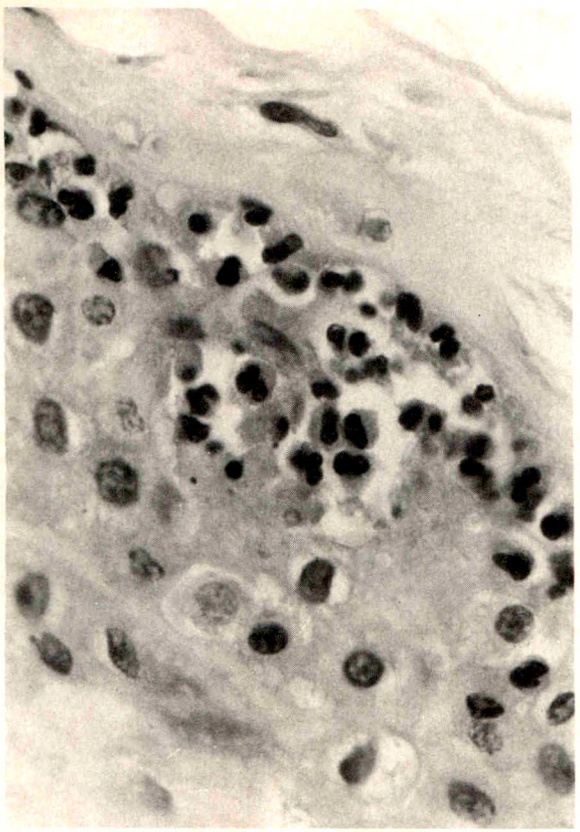

Fig. 1. Maternal leukocytes are collecting in trophoblastic cell layer of chorion. There is already significant destruction of much of this cell layer. However, none of infiltrate has progressed into mesodermal connective tissue of chorion, which lies above. Trophoblastic cell layer is about six cell layers thick, which is characteristic of late second trimester or early third trimester chorion. Maternal decidua lies below.

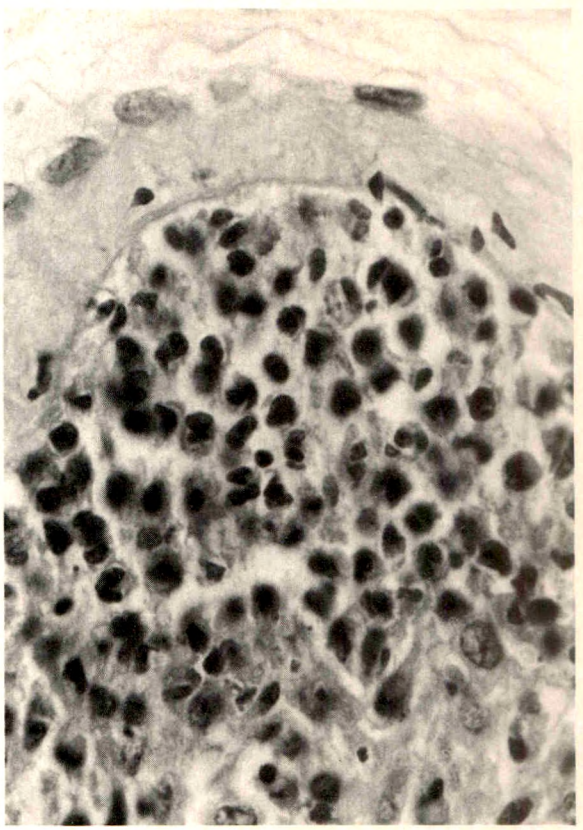

Fig. 2. Although trophoblastic cell layer of chorion has been destroyed there is still no infiltrate in connective tissue above trophoblastic cell layer. Amnion is out of illustration above.

gestational age agreed with that predicted by the stated last menstrual period, at least one antepartum ultrasonographic estimate, and the delivered infant. Gestational age was rounded to the nearest even-numbered week. The histologic slides were then examined by light microscopy with particular attention given to the trophoblastic cell layer of the chorion. As the material had not been collected prospectively or quantitatively it was possible only to estimate the amount of any given histologic feature. However, placentas had been processed by a modification of the method suggested by Benirschke and Driscoll[9]; therefore in each case there was a section of rolled fetal membrane on file. We also examined the remnants of the cytotrophoblastic shell in the decidua beneath the placenta proper. This material was more fragmentary.

Results

Table I lists the amount of material obtained at each gestational age. The 121 cases were clinically heterogeneous. Elective cesarean deliveries and cases complicated by maternal diabetes or toxemia were included. However, with the exception of abruptio placentae and chorioamnionitis, no associated clinical condition produced any apparent difference in the histology of the membranes other than that difference attributable to gestational age alone. This difference is described below.

A total of 18 cases from pregnancies terminated between 18 and 26 weeks' gestation all showed histologic chorioamnionitis. The trophoblastic cell layer was the first fetal layer to be infiltrated by maternal leukocytes (Fig. 1). The leukocytes accumulate in this layer before they move into the overlying mesoderm. Their presence was associated with near destruction of this layer, so that by the time they moved into the overlying mesoderm the trophoblast cell layer was gone (Fig. 2). Subsequently they tended to form in another layer immediately beneath the compact zone that supports the amnion. Then microabscess formation occurred followed by destruction and loss of the overlying amniotic epithelium. In the one case of abruptio placentae seen in this gestational age group, blood dissected between the maternal decidua and the trophoblast.

As expected,[9] the incidence of chorioamnionitis fell after 26 weeks' gestation. From a total of 29 cases dated from 28 through 32 weeks' gestation, 14 (50%) showed

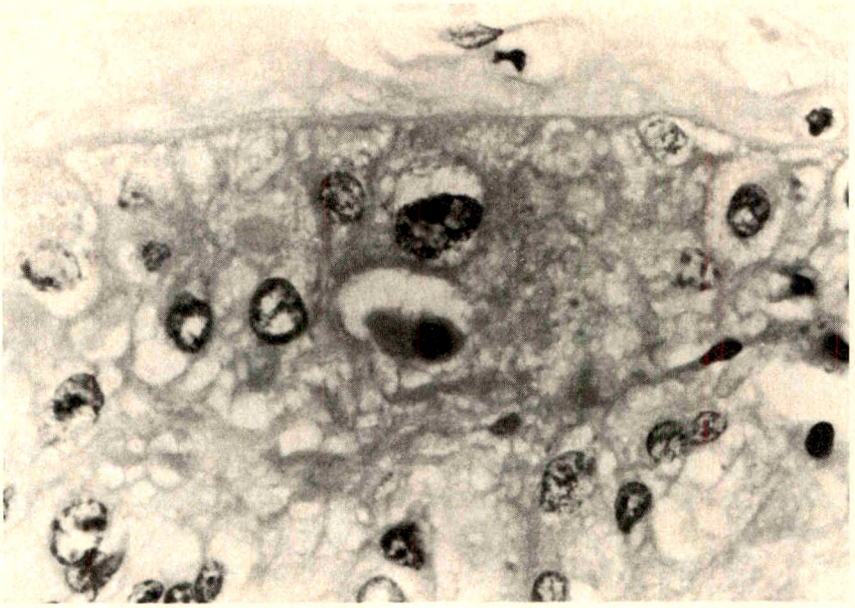

Fig. 3. One cell with dark shrunken nucleus and eosinophilic shrunken cytoplasm around it lies in middle of illustration. It appears to have withdrawn from normal tissue around it. Just above this cell, another cell may be beginning very early apoptosis as indicated by some nuclear condensation. This example of trophoblastic cell layer is about four or five cell layers thick. Although this feature is variable and may be affected by angle of section, it is fairly typical of membranes from early to middle third trimester.

chorioamnionitis. As described above, the trophoblastic cell layer was infiltrated and destroyed early in the process. In the 15 cases without chorioamnionitis, scattered individual cells within the trophoblastic cell layer exhibited the characteristic histology of apoptosis or spontaneous cell death. There was no associated inflammatory reaction. Described in detail by Searle et al.,[2] apoptosis consists of the shrinkage of both nucleus and cytoplasm. The nucleus becomes condensed and dark and eventually fragments (Fig. 3). The cytoplasm becomes highly eosinophilic and may be irregularly contracted so that cytoplasmic projections exist (Figs. 4, 5). The whole cell, now smaller, seems to shrink away from its neighbors, which are normal in appearance. Homogenous eosinophilic material, deposited focally in the cell layer where cell death had occurred, was similar in appearance to eosinophilic material deposited over placental trophoblast called the Nitabuch layer. This eosinophilic material tends to disappear as term is approached. In the two cases of abruptio placentae between 28 and 32 weeks' gestation, retroplacental blood had dissected into the space between the trophoblast and the decidua.

Of the 30 cases dated between 34 and 36 weeks' gestation, nine showed chorioamnionitis. In the rest, apoptosis was much more prevalent than in the 28- to 32-week material. By 36 weeks' gestation, there were foci where the trophoblastic cell layer was absent, and maternal decidua was directly opposed to fetal connective tissues (Fig. 6). Many of these sites lack even the eosinophilic material. In one case, there was a purely local, chronic inflammatory reaction that was quite dissimilar to the acute reaction observed in chorioamnionitis.

From 38 to 42 weeks' gestation there were 43 total cases. Two showed chorioamnionitis. The histology of one case of chorioamnionitis at 42 weeks' gestation was unusual in that the minimal inflammatory infiltrate did not initially concentrate in the trophoblastic cell layer, because this cell layer was absent. Apoptosis was widespread. The maternal decidua was in direct contact with fetal connective tissue at multiple sites.

At all gestational ages the delivered placentas possessed only fragments of the decidua basalis. Thus, thorough study of the fate of those trophoblastic cells that infiltrate the implantation site was not possible. However, our impression was that they share the same histologic fate as the trophoblastic cells in the chorion laeve.

In only one instance did the criteria outlined in our methods section convincingly suggest a 44-week pregnancy. The histology of the membranes was consistent with that view. There was relatively massive thinning of the trophoblastic cell layer. Maternal decidua and fetal connective tissue were in direct contact over broad

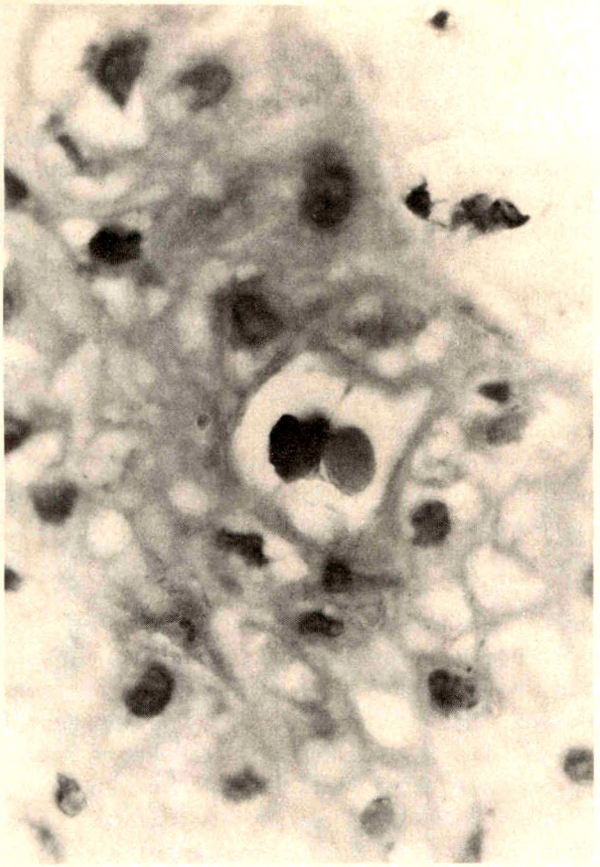

Fig. 4. Two apoptotic cells are seen in trophoblast. At right is eosinophilic cell body of one that has shrunken from the normal tissue around. At left, cytoplasm of second cell is not clearly discerned because of dark pyknotic nucleus.

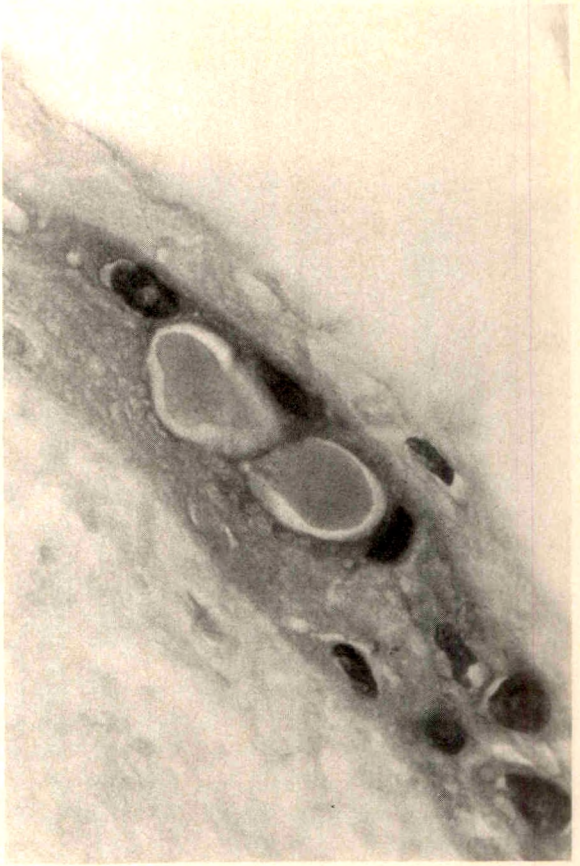

Fig. 5. Two cells have become apoptotic side by side. Nuclear fragments are not apparent in these cells and only their dense eosinophilic cytoplasm is seen shrinking from tissue around them. Early apoptotic changes in adjacent cells may be indicated by their increasingly dense nuclei. This example of trophoblast cell layer of chorion is about two or three cell layers thick, which is fairly characteristic of chorionic membranes from late third trimester.

areas. Extensive apoptosis characterized those sites of remaining trophoblast.

In summary, the trophoblastic cell layer of the chorion laeve had widespread apoptotic cell death and loss of the trophoblastic cell layer as term approached. In cases complicated by chorioamnionitis, the same tissue was prematurely destroyed by the maternal inflammatory infiltrate. This occurred very early in the course of the development of chorioamnionitis.

Comment

We have drawn two conclusions. The first is that trophoblast in the chorion laeve thins and progressively disappears as term is approached. Individual cell death, apoptosis, is a prominent histologic feature of this process. The fact that apoptosis characterizes this process is a new observation but the fact that the trophoblast in the chorion laeve disappears in a patchy manner as term nears is not new. In 1962 Bourne[10] described the histology of the chorioamnion in detail. Most of his material was obtained from deliveries that occurred at term and his description is of term membranes. However, he did have enough preterm material to recognize that some of the observations he made on term membranes represented changes that occurred as term approached. An example was what he called "degenerative changes" in the trophoblastic cell layer of the chorion. The cells of this layer were replaced by "granular, fibrin-like material." These were "diffusely scattered as irregular plaques" over term membranes. He believed that they were often associated with necrosis of the underlying decidua.

The second conclusion is that the trophoblastic cell layer of the chorion laeve is destroyed very early in the course of chorioamnionitis by the maternal inflammatory infiltrate. Although this observation is not new,

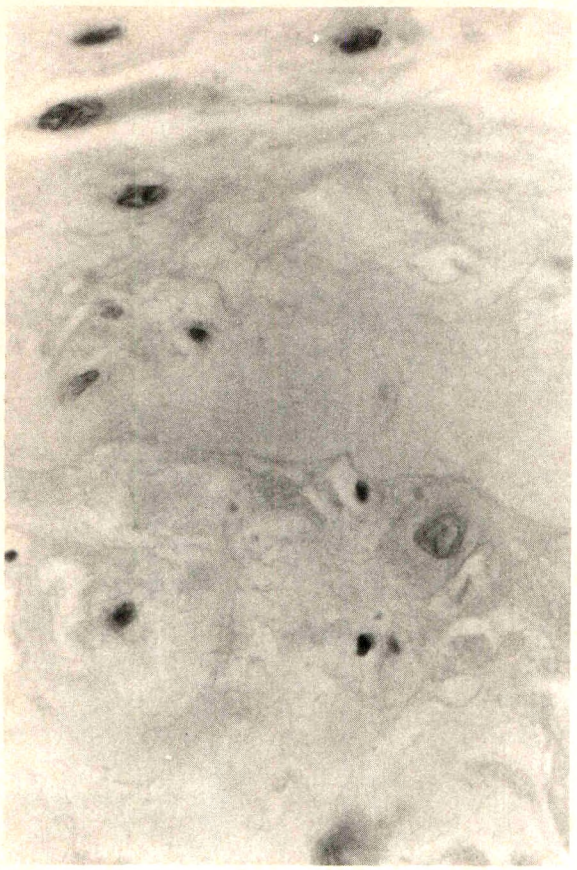

Fig. 6. Above lies mesodermal connective tissue of chorion. Amnion is out of illustration above. Below is maternal decidua, which lies immediately adjacent to connective tissue of chorion with no intervening trophoblast. One degenerating cell may represent remnants of trophoblastic cell layer.

Table I. Placentas examined

Gestational age (wk)	*No. of cases*	*Abruptio placentae*	*Chorioamnionitis*	*Frequency of apoptosis*
18	1	—	1	Obscured by chorioamnionitis
20	2	—	2	—
22	4	—	4	—
24	3	—	3	—
26	8	1	8	—
28	7	1	3	+
30	6	—	3	+
32	16	1	8	+
34	14	—	5	+ + +
36	16	—	4	+ + +
38	19	—	1	+ + + +
40	13	—	—	+ + + +
42	11	—	1	+ + + +
44	1	—	—	+ + + +

little emphasis has been given to how early in the course of the inflammatory process the trophoblastic cell layer may be destroyed.

More speculatively, if it is suggested that the life span of the trophoblastic cell layer of the chorion laeve, under physiologic or some pathologic conditions, measures the length of gestation, then this view is consistent with much of the current thinking about the onset of parturition.[11] Rising amniotic fluid levels of glucocorticoids after 30 weeks' gestation might induce apoptosis in the chorion laeve.[12] Glucocorticoids are known to induce apoptosis,[7] and prednisolone produces premature trophoblastic death in the placenta of rodents.[13] Moreover, anencephaly, a condition associated with prolonged gestation, results in the biologic opposite of apoptosis. The trophoblast in the body of the placenta of an anencephalic fetus fails to morphologically mature in human beings.[14]

The loss of the trophoblast in the chorion laeve would be expected to result in a local decrease in anything the trophoblast produces, including progesterone.[15] It also might include a decrease in the ability to metabolize any locally produced prostaglandin.[16, 17] Further, if amniotic fluid factors are important in the initiation of labor then the loss of a tissue between the amniotic fluid and the maternal decidua might result in increased transfer of the amniotic fluid factors to the maternal tissues.[11] The gradual rather than acute loss of the trophoblastic cell layer would be consistent with the inability (to date) to show any dramatic changes in hormone physiology immediately before the onset of parturition.

In the case of chorioamnionitis, if the life span of the trophoblastic cell layer of the chorion laeve measures the length of gestation then the premature destruction of the trophoblastic cell layer by maternal leukocytes would result in premature labor. This destruction might occur either because of the initiation of the physiologic mechanism suggested above or in response to other components of the inflammatory reaction released incidental to the maternal leukocytic infiltration, such as cytokines or prostaglandins.[18] The very early and nonspecific nature of this event would be consistent with the high but less than universal correlation of premature labor, histologic chorioamnionitis, and documented infection.[19, 20]

In any case the widespread loss of the trophoblastic cell layer in a 44-week pregnancy and the presence of relatively large amounts of trophoblast in some cases of premature labor is strong evidence that the relationship of the life span of this tissue to the length of gestation is not a simple one. Furthermore, if the life span of the extraplacental trophoblast is important in timing the length of gestation, then the trophoblast that infiltrates the decidua basalis and has not been studied cannot be ignored.

Grateful acknowledgement is extended to Dr. Norman Dubin for his helpful criticism of both the ideas and the manuscript at all stages in its production.

Discussion

Dr. Daniel K. Roberts, Wichita, Kansas. The author's demonstration that trophoblastic epithelium of the chorion laeve disappears as gestational term approaches is not new information. However, it is new information that the process responsible for this phenomenon is apoptosis. This is important because it suggests that the tissue loss is a physiologic process rather than nonspecific degeneration. The process of an orderly maintenance and termination of gestation is the most likely explanation.

The author further shows that the maternal inflammatory infiltrate associated with chorioamnionitis destroys the same tissue layer that spontaneously disappears as term nears. This destruction takes place very early in the course of the development of chorioamnionitis. If the trophoblast of the chorion laeve is responsible for the maintenance of gestation, then its destruction by maternal leukocytes would promote the termination of gestation, and thus provide a link between chorioamnionitis and premature delivery.

The author appropriately points out that some of his observations are inconsistent with his hypothesis. Some examples of prematurely delivered placentas without chorioamnionitis still have much of their trophoblastic tissue. In another case, labor had not begun until 44 weeks' gestation despite extensive loss of the trophoblastic layer. These cases could be explained by individual variation or by unknown pathophysiology. I would like the author to comment further on this.

The speculation that apoptosis is the mechanism that controls gestational termination provides the principal interest in this article, but as the author correctly points out, only morphologic conclusions can be reached from morphologic studies. I look forward to the experimental studies that might confirm or refute this possibility. These might include comparative studies with other animals in addition to more quantitative studies. Ultrastructural evaluation might also be interesting.

In addition to the comment with regard to discrepant findings, I would like to ask the author:

1. You indicate that in apoptosis "other factors" rather than inherent timing are the primary causes. Please explain further.

2. If apoptosis is the manner of destruction in premenstrual endometrium, why are neutrophils present during that phase?

3. If apoptosis is a time-mitigated response, how might it play a role in the aging process?

4. What role do you believe this mechanism plays in the initiation of labor?

Dr. Michael W. Varner, Salt Lake City, Utah. Professional communications in clinical medicine can vary from case reports, through retrospective or prospective series, to prospective, randomized trials. All these formats have been of value in obstetrics and gynecology. However, all these formats also have potential hazards that must be considered before their conclusions can be accepted.

This study is a retrospective series describing histologic changes in chorioamnionic membranes. As with any retrospective study, questions must be routinely asked about patient selection criteria, operational definitions, associated complications and conditions, and

potential unavailability of confirmatory evaluations and laboratory or research tests.

A total of 121 patients of clinically certain gestational age were included in this report. They were collected during a 6-month interval when all placentas were routinely submitted for pathologic evaluation. This strikes me as a small number for a university referral service and I wonder whether any statistical calculations were undertaken to address the question of adequate sampling.

The major dependent histologic variables are the progressive decline in histologic chorioamnionitis and increase in apoptosis with progressive gestational age. Whereas associations seem to be present, I always worry when cases are evaluated in a nonblinded fashion and would suggest that these findings be confirmed in a prospective, blinded study.

In the manuscript, chorioamnionitis is only defined in histologic terms. I wonder how chorioamnionitis is clinically defined on the author's service and what proportion of patients had this clinical condition? The manuscript states that the histologic changes occurred early in the course of the development of chorioamnionitis and I wonder how closely the clinical diagnosis correlated with the histologic diagnosis?

Any information about associated complications and conditions would be both informative and potentially suggestive of coexistent explanations or causes. Elective cesarean deliveries were included. Does the absence of labor affect the frequency or intensity of the histologic findings? Did any of the patients receive antenatal steroids? I wonder what proportion of women, particularly in the preterm group, had premature rupture of the membranes?

In addition, were any of the pregnancies associated with other conditions, such as fetal asphyxia, that might predispose them to leukocytic infiltration?

A final hazard of any retrospective series is the potential subsequent unavailability of confirmatory evaluations and laboratory or research tests. What proportion of these women had cultures performed of their amniotic fluid, chorioamnionic membranes, placentas, uteri, or newborns? In the absence of confirmatory cultures the diagnosis of chorioamnionitis must be considered questionable.

It would also be interesting to correlate these changes with presumptive biochemical markers of labor such as prostaglandin metabolites. Romero and associates[1] have shown that prostaglandin E_2, prostaglandin $F_{2\alpha}$, and their respective metabolites are elevated in the amniotic fluid of women with intraamniotic infection and preterm labor. In the absence of intraamniotic infection, the elevation in premature labor is modest. In the future it might also be interesting to correlate these findings with endogenous host-response products to presumed infection such as tumor necrosis factor or interleukin-1.

I would like to address a subpopulation of this study that I think is of particular importance and significance, namely, those patients between 26 and 32 weeks' gestation. Before 26 weeks' gestation, neonatal outcome is usually bad and beyond 32 weeks it is usually good. A total of 50% of patients in this intermediate group had histologic chorioamnionitis. I wonder whether these histologic findings correlate with perinatal parameters such as clinical asphyxia or respiratory distress syndrome. If they do we might be able to develop a screening or predictive test that could identify premature labor patients at highest risk for suboptimum outcomes.

Dr. L. Russell Malinak, Houston, Texas. In a majority of the slides without chorioamnionitis, there was a single cell or only two cells with this change. What is the fate of the healthy looking cells, and are they candidates for this same process? If so, why did we not see histologic evidence of that process in more cells?

Dr. Edgar L. Makowski, Denver, Colorado. Dr. Parmley, were the membranes that were examined consistently obtained from the same location? Second, the slides that you projected with destruction of the trophoblastic cells appear rather avascular. As a result, do you see any evidence of destruction of the accompanying vascular bed? This would be of great clinical significance because there would be a decrease in the density of the vascular bed and it could affect the transport of nutrients and respiratory gases.

Dr. Dinesh M. Shah, Nashville, Tennessee. In the presentation by Dr. Parmley, there is an inherent assumption that the mechanism for maintenance of gestation resides in the existence of the trophoblastic cells in the chorion laeve. The current overwhelming endocrine evidence would suggest that it probably resides in the placenta. In the same light, I have a question. If the primary contribution of chorion laeve at the present time is recognized as substrate availability for prostaglandin metabolism, what is the interrelationship between apoptosis in the contribution to the prostaglandin metabolism by the chorion laeve?

Dr. Parmley (Closing). There is a difference between histopathologic reality and clinical reality and this manuscript is a description of an aspect of histopathologic reality. For example, clinical chorioamnionitis is a different entity than histopathologic chorioamnionitis. Many of the criteria that are required to make the diagnosis of clinical choriamnionitis are not present in the cases presented here, but they are not present because it is not the purpose of these observations to make clinical statements. Pathologic chorioamnionitis is the topic under discussion and the gold standard for the diagnosis of pathologic chorioamnionitis is the histologic picture I have just shown you.

As a further illustration, when I made the statement in this presentation that the case was an early example of chorioamnionitis, that statement was made on the

basis of the histologic observation that the leukocytes have not moved very far in the tissue. That is the appropriate pathologic definition of early. It may be totally irrelevant to the clinical diagnosis of early, but it is the appropriate pathologic one.

Many of these examples of histologic chorioamnionitis were in patients who did not show evidence of chorioamnionitis by culture or by symptoms in either mother or infant.

Cases were selected as follows. The placentas from every delivery over a 6-month period were collected. They were processed by a modification of Benirschke's method so that there was a rolled section of fetal membrane available from each placenta. If a review of the records suggested an accurate gestational age then the case was selected for study. Most clinical cases can not be so accurately dated and therefore only a small portion of the total number of placentas was actually examined.

Dr. Roberts asked about natural variation. Whatever the mechanisms for maintenance and termination of pregnancy are, they are undoubtedly characterized by fail-safe mechanisms. That is, they are highly complex and do not depend on any single variable. Consequently, in looking at any single variable, even if it is important, one would encounter a great deal of variation.

We have looked at animals. What the placentas of other mammals show is a similar histology but it is much more acute. That is, in animals this same thing happens but it happens very acutely and over a very short period of time, which tangentially brings me to the question asked by Dr. Malinak.

Apoptosis lasts in the tissue for at most 3 or 4 hours. If you see one example in a tissue section, then the process is taking place very rapidly within that tissue. Placentas near term occasionally show high power fields in which there are two or three examples. I illustrated one stretch of membrane that had multiple examples of it. That means a massive amount of apoptosis is occurring in a very short period of time.

Another question that Dr. Roberts asked was whether factors other than natural cell death can cause apoptosis. The list is a mile long and includes a variety of hormones, perhaps significantly, corticosteroids.

Neutrophils are in the menstruating endometrium as it sloughs, that is, as necrosis is taking place. The apoptosis that takes place in the menstruating endometrium takes place before this time.

Dr. Roberts asked about the relationship of this phenomenon to aging. There is not necessarily such a relationship but the life span of species has been hypothesized to be controlled by a clock similar to the one that is suggested here. A putative stem cell population for the soft tissue might be a sight for such a clock.

Dr. Makowski asked about the site of the membranes. These were randomly selected sections. He also asked about decreased vascularity. Acute decreases in vascularity produce necrosis. Minimal decreases in vascularity were not something we noted.

I agree with the comment from Dr. Shah that these observations raise the possibility that the trophoblast of the chorion laeve is important in the maintenance of pregnancy. I did not speak to that because the suggestion is an indirect one and I do not feel knowledgeable enough to address it. And with respect to the biochemical questions that were raised, I am afraid that this poor old morphologist would make a sad fool of himself if he commented on biochemistry.

Flow cytometric evaluation of epithelial ovarian cancer

Vanessa M. Barnabei, MD, PhD,[a] David Scott Miller, MD,[a] Kenneth D. Bauer, PhD,[b] Tariq M. Murad, MD,[b] Alfred W. Rademaker, PhD,[c] and John R. Lurain, MD[a]
Chicago, Illinois

We investigated the prognostic significance of deoxyribonucleic acid content and proliferative activity of tumor cell populations as measured by flow cytometry of the tumor specimens from 115 women with epithelial ovarian cancer. Deoxyribonucleic acid aneuploidy was found in 87 of 115 (76%) of these cancers with a mean deoxyribonucleic acid index of 1.6 and S-phase fraction of 14.7%. The S-phase fraction of the 28 (24%) diploid tumors was 7.0%. Deoxyribonucleic acid ploidy was significantly correlated with survival. S-phase fraction was significantly correlated with ploidy, residual tumor, histology, grade, ascites, time to recurrence, and survival. Diploidy versus aneuploidy were the best discriminating values for deoxyribonucleic acid index and an S-phase fraction of greater or less than 18% for that parameter. Multivariate analysis revealed stage, S-phase fraction, residual tumor, and grade to be independently associated with time to recurrence, and stage, age, S-phase fraction, and largest metastases were factors associated with survival. Deoxyribonucleic acid ploidy did not significantly improve either model. These results suggest that abnormalities of deoxyribonucleic acid content and the proliferative activity of tumor cell populations are reflective of their biologic activity. (Am J Obstet Gynecol 1990;162:1584-92.)

Key words: DNA flow cytometry, ovarian cancer, S-phase fraction

Cancer of the ovary is the leading cause of death among gynecologic malignancies in the United States. Improvements in surgical and chemotherapeutic regimens have had minimal effect on long-term survival. Traditional parameters, such as stage, histologic grade, and tumor burden, have been used to stratify patients into broad prognostic groups.[1] Newer methods, such as the quantitation of deoxyribonucleic acid (DNA) content by flow cytometry, may prove to be more reliable in predicting outcome in ovarian cancer patients. Flow cytometry has been shown to be an objective method of quantitating cellular DNA content and proliferative activity in normal and neoplastic cell populations.[2, 3] Blumenfeld et al.[4] in this country and several investigators[5-10] abroad have reported a strong correlation between ploidy and outcome in women with epithelial ovarian cancer. Only one of these studies discussed ploidy abnormalities in relation to disease progression and time to recurrence.[9] We report the correlation of tumor ploidy, DNA index, and S-phase fraction with other known prognostic factors and on survival and recurrence for all stages of epithelial ovarian cancer.

Material and methods

Patient data. The medical records of 115 women with epithelial ovarian cancer diagnosed and treated at Northwestern Memorial Hospital between 1978 and 1987 were reviewed with respect to multiple clinical parameters, as shown in Table I.

Pathologic studies. Original histopathologic slides from the above patients were reviewed by one of us (T. M. M.) to ensure that there was adequate tumor tissue in the blocks used for flow cytometry. All cases were reviewed without knowledge of the clinical outcome. After confirming the diagnosis, the cases were classified according to their histologic types as presented by the World Health Organization in 1973[11] and reiterated by Scully in 1977.[12] Tumors of low malignant potential will be reported elsewhere. The tumors were graded as well-differentiated (grade 1), moderately differentiated (grade 2), and poorly differentiated (grade 3) tumors. The well-differentiated carcinomas were characterized by well-formed papillae with fibrovascular cords and no solid components. Grade 2 tumors were partially solid and glandular. The poorly differentiated tumors were recognized when the carcinoma was primarily solid with little or no glandular formation. Mitoses and nuclear pleomorphism were more often seen in high-grade tumors than low-grade

tumors, but these features were not used primarily for grading.

For flow cytometry study the blocks were selected when the entire tissue was represented by the malignancy. In those cases in which benign tissue was noted adjacent to the tumor, the cancerous area was identified by a permanent marker on the paraffin block.

Flow cytometry. The corresponding paraffin-embedded blocks were dewaxed with xylene and rehydrated with a modification of the method originally described by Hedley et al.[13, 14] The tissue was then pepsin treated and resuspended in Hepes-Hanks media. After treatment with ribonuclease I (180 U/ml), the cells were stained with propidium iodide (50 mg/ml) as detailed previously.[14] Cellular DNA content was measured on a Coulter Epics 752 flow cytometer (Coulter Electronics, Hialeah, Fla.). The data were presented as DNA fluorescence histograms from which cell cycle analysis (percent G_1, percent S, percent G_2M), DNA ploidy, and DNA index were calculated. The coefficient of variation about the major G_1G_0 peak on the DNA histogram ranged from 1.0% to 6.9% in these studies (mean, 4.42%). Cases with a coefficient of variation greater than 7.5% were excluded from DNA ploidy and cell cycle analysis. DNA aneuploidy was defined only on the basis of the presence of two distinct G_1/G_0 peaks in the DNA histogram. DNA index was defined as the mean fluorescence of the DNA aneuploid peak divided by that of the DNA diploid peak. This measurement thus provides an indication of the degree of alteration or change in DNA content in relation to diploid cases (DNA index = 1.0). The percentage of S = phase cells was calculated by the MCYCLE software (Phoenix Systems, Inc.) according to a modification of the method of Dean and Jett.[15] Proliferative activity in this investigation was reported on the basis of the percentage of cells in S phase because this calculation has been reported to be a more precise estimate than calculations of the percentage of G_2M.[16]

Statistical methods. Time to recurrence and survival were calculated from the date of primary operation. The tests used to compare DNA index and S-phase fraction with clinical parameters, such as stage, grade, histology, and residual tumor, were χ_2 and analysis of variance.[17] Kaplan-Meier product limit estimates,[18] Breslow's generalized Wilcoxon test,[19] and Cox regression analysis were used to evaluate the association of S-phase fraction and the other factors to recurrence and survival.[18] Hazard ratios indicate the change in the risk of recurrence or death per unit change in percent S phase. Stepwise Cox multivariate regression analysis was used to assess the relative order of importance of clinical parameters to recurrence and survival time. Data analysis was performed with BMDP statistical software.[20] Statistical significance was defined as values of $p < 0.05$.

Results

Of the 115 patients evaluated, 17 (15%) had stage I disease according to International Federation of Gynecology and Obstetrics criteria, 13 (11%) had stage II disease, 61 (53%) had stage III, and 24 (21%) had stage IV disease. After primary tumor debulking, 29 (25%) patients were left with no residual tumor, 43 (37%) had implants <2 cm, and 38 (33%) had residual tumor implants >2 cm. The correlation of stage and residual tumor is shown in Table II. As seen in Table III, most cancers were serous histologically and poorly differentiated.

DNA aneuploidy as defined by a DNA index other than 1.0 was found in 76% of these tumors (87/115). The mean ± SE DNA index of the aneuploid cancers

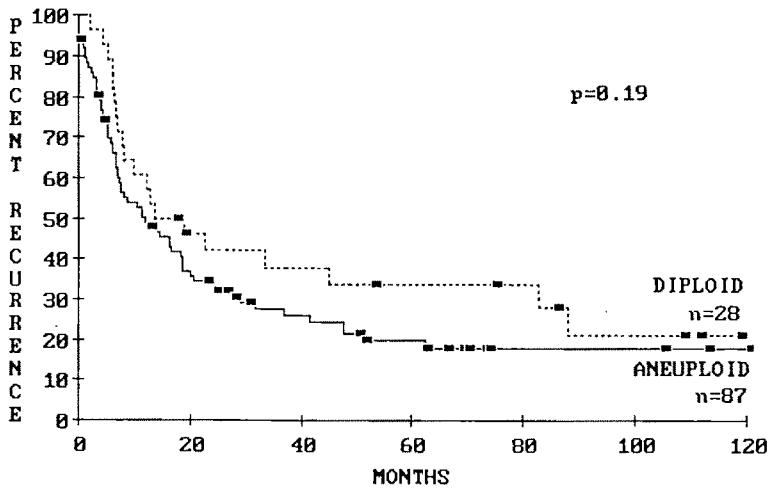

Fig. 1. Time to recurrence product limit curves for diploid (n = 28) versus aneuploid (n = 87) DNA index, p = 0.04.

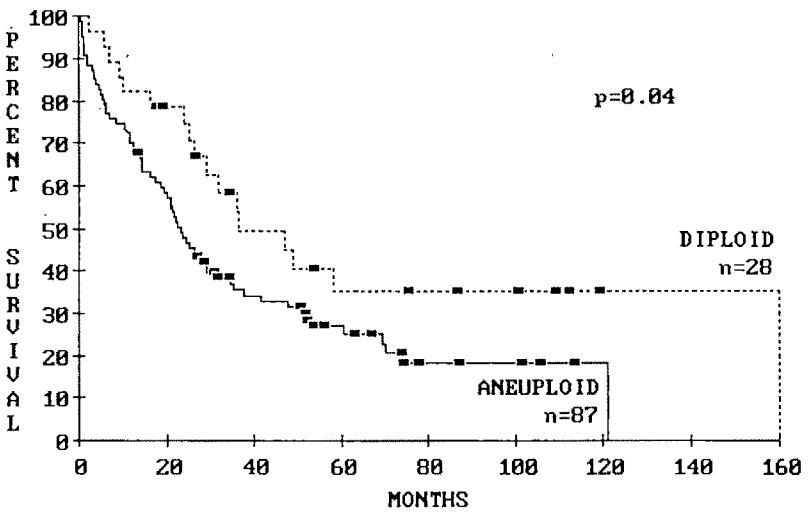

Fig. 2. Product limit survival curves for diploid (n = 28) versus aneuploid (n = 87) DNA index, p = 0.19.

Table II. Stage versus residual tumor

	Residual tumor								*Total*	
	None		*<2 cm*		*>2 cm*		*Unknown*			
Stage	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
I	15						2		17	15
II	10		2		1				13	11
III	4		33		22		2		61	53
IV			8		15		1		24	21
Total	29	25	43	37	38	33	5	4	115	100

Residual tumor was not described in five patients. χ^2, p = 0.0001.

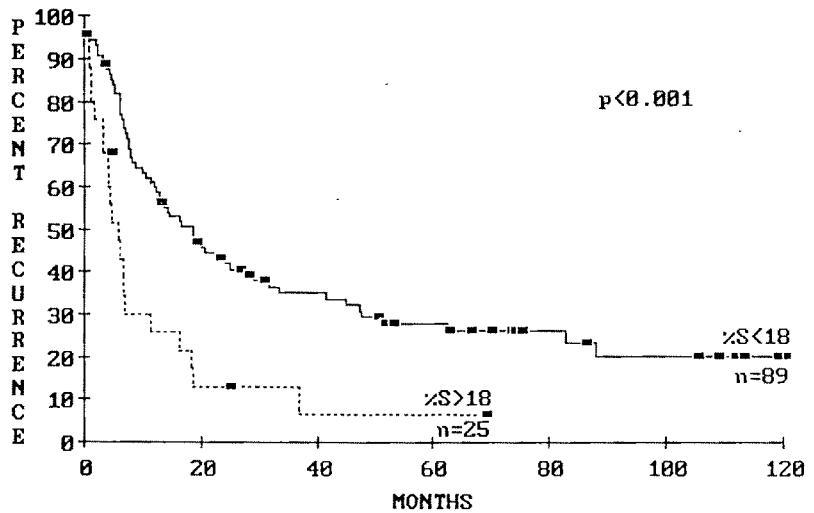

Fig. 3. Time to recurrence product limit curves for S-phase fraction <18% (n = 89) versus > 18% (n = 25), $p < 0.001$.

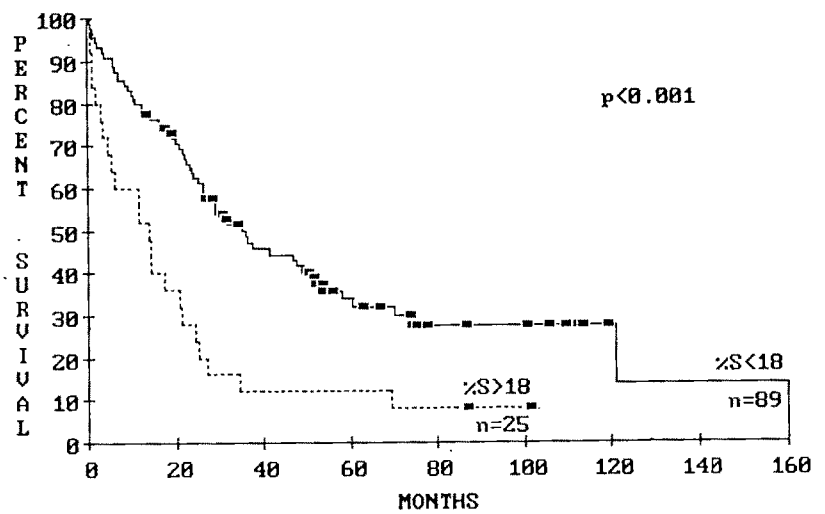

Fig. 4. Product limit survival curves for S-phase fraction < 18% (n = 89) versus >18% (n = 25), $p < 0.001$.

was 1.60 ± 0.04 and the S-phase fraction of cells 14.7% ± 0.9%. The S-phase fraction of the 28 (24%) diploid cancers was 7.0 ± 0.8. Aneuploidy and S-phase fraction were correlated ($p < 0.0001$). The results of flow cytometry in relation to the factors listed in Table I were analyzed and correlated ones are displayed in Tables IV through VIII. Histologic type and grade correlated with tumor ploidy (Tables VI and VII). S-phase fraction was significantly correlated with residual tumor, histologic type, grade, and ascites (Tables V through VIII).

With a minimum follow-up time of 30 months, 83 of 115 patients have died (72 of cancer, 8 of complications, and 3 of other causes). Of the remaining 32 patients, 24 are alive without evidence of disease and 8 are alive with disease. Median time to recurrence was 13 months and median length of survival was 26 months.

Tumor ploidy and S-phase fraction were correlated with time to recurrence and survival. DNA ploidy correlated with survival ($p = 0.04$), whereas S-phase fraction was correlated with time to recurrence (hazard ratio = 1.04, $p = 0.0008$) and survival (hazard ratio = 1.04, $p = 0.0013$).

Time to recurrence and survival time versus DNA index were evaluated by product-limit survival analysis. Tumor diploidy versus aneuploidy was the best prog-

Table III. Histologic type versus grade

χ^2, $p < 0.0001$.

Table IV. Stage, DNA ploidy, and S-phase fraction

	Aneuploid		% S-phase fraction
Stage	No.	%	(mean ± SE)
I	10/17	59	9.5 ± 2.1
II	9/13	69	10.2 ± 1.9
III	49/61	80	13.1 ± 0.9
IV	19/24	80	15.9 ± 2.1
	$p = 0.29$		$p = 0.059$

Table V. Residual tumor, DNA ploidy, and S-phase fraction

	Aneuploid		% S-phase fraction
Residual tumor	No.	%	(mean ± SE)
0 cm	20/29	69	9.7 ± 1.5
≤2 cm	34/43	79	13.8 ± 1.2
>2 cm	30/38	79	15.0 ± 1.4
	$p = 0.55$		$p = 0.027$

Table VI. Histologic type, DNA ploidy, and S-phase fraction

	Aneuploid		% S-phase fraction
Histologic type	No.	%	(mean ± SE)
Serous	56/67	84	14.9 ± 1.0
Mucinous	7/10	70	9.1 ± 2.4
Endometrioid	13/23	56	10.7 ± 1.8
Clear cell	2/4	50	5.1 ± 0.7
Adenocarcinoma	9/11	82	10.9 ± 2.6
	$p = 0.069$		$p = 0.017$

nostic discriminator for DNA index. The median time to recurrence was 14 months for the diploid tumors and 11 months for the aneuploid tumors ($p = 0.19$) (Fig. 1). The median patient survival was 36 months

Table VII. Grade, DNA ploidy, and S-phase fraction

	Aneuploid		% S-phase fraction
Grade	No.	%	(mean ± SE)
1	9/17	53	7.2 ± 1.7
2	27/36	75	13.5 ± 1.4
3	49/60	82	14.3 ± 1.0
	$p = 0.053$		$p = 0.006$

Table VIII. Ascites, DNA ploidy, and S-phase fraction

	Aneuploid		% S-phase fraction
Ascites	No.	%	(mean ± SE)
Present	52/64	81	14.5 ± 1.1
Absent	25/37	68	11.0 ± 1.2
	$p = 0.19$		$p = 0.042$

for the diploid tumors and 23 months for aneuploid tumors ($p = 0.04$) (Fig. 2). An S-phase fraction of 18% was the best prognostic discriminating level of that variable. The median time to recurrence was 17 months for those fractions <18% and 5 months for those >18% ($p < 0.001$) (Fig. 3). The median survival was 32 months for those <18% and 12 months for those >18% ($p < 0.001$) (Fig. 4).

The other parameters listed in Table I were correlated with outcome by univariate analysis. Stage and residual tumor, the diameter of the largest metastases, ascites, and size of residual tumor were significantly associated with time to recurrence and survival ($p < 0.001$). Primary tumor diameter was associated with time to recurrence ($p = 0.04$). Survival was also assocociated with age ($p = 0.0097$).

On the basis of results of univariate analysis and other studies,[1] 10 factors were chosen for analysis by Cox multivariate stepwise regression. The variables that

were independently associated with time to recurrence were stage, S-phase fraction, residual tumor, and grade (Table IX). There was no significant improvement in the model by the addition of DNA ploidy. However, stage, age, S-phase fraction, and largest metastasis diameter were independently associated with survival (Table X). DNA ploidy did not significantly improve the survival model.

Table IX. Cox multivariate analysis of time to recurrence

Step	*Variable*	*p to Enter*

10	Histologic type	0.52
11	Primary tumor diameter	0.67

Comment

The application in recent years of DNA flow cytometry has provided supplemental information regarding prognosis for women with epithelial ovarian cancer. Our results demonstrate that tumor ploidy and S-phase fraction are prognostic factors in epithelial ovarian cancer. This is a consistent finding in other recent reports,[5-10] although the importance of flow cytometry results in multivariate analysis varies from study to study. In our analysis, S-phase fraction was predictive of recurrence and survival, with 18% being the most sensitive predictor for that variable. This suggests that proliferative activity significantly influences the clinical behavior of these tumors, such that tumors with a high percentage of actively dividing cells behave in a more aggressive manner.

Review of the literature reveals a considerable range in the frequency of aneuploidy detected in epithelial ovarian tumors, from a low of 52% to a high of 81%. Factors that may influence the frequency of aneuploidy include the stage of disease (i.e., inclusion of early stage disease), the type of tissue analyzed (i.e., fresh versus paraffin blocks), the area of tumor analyzed, and the sensitivity of the techniques and instrumentation used. For this study, the original histopathologic slides were reviewed by a single individual (T.M.M.) without knowledge of clinical outcome; areas of high tumor density were marked for flow cytometry. This process may be more time-consuming than the use of fresh tissue or random blocks, but we believe that it lends consistency to our results and provides an accurate assessment of tumor aneuploidy in our patient population.

Of the recent studies in the literature, only Rodenburg et al.[9] have addressed the issue of flow cytometry on progression-free interval. In their analysis, as in ours, ploidy was dropped out as an independent prognostic factor in multivariate analysis. However, S-phase fraction, stage, residual tumor, and grade were predictive of time to recurrence and survival by multivariate analysis in this study.

The dismal survival of patients with aneuploid tumors and those with high S-phase fraction suggests inherent differences exist between these tumors and diploid tumors. Although flow cytometry quantitates cellular DNA content and proliferative activity, it can provide an indirect measure of qualitative differences in cellular function and may be useful in understanding the biologic characteristics of malignancy. Chromosomal instability and gene amplification cause abnormalities in DNA content that can be detected by flow cytometry. There is evidence that the latter, at least, directly confers drug resistance to some cells.[21] In addition, DNA rearrangements may contribute to drug resistance and increased malignant behavior by altering expression of single genes, such as enzymes and other proteins involved in DNA repair and drug uptake. Increasing aneuploidy and S-phase fraction with disease stage suggest an ongoing process leading to accumulation of lesions, both at the chromosomal and gene level, which in turn contributes to further invasive behavior and drug resistance. This is consistent with the Goldie-Coldman[22] hypothesis of the genetic origin of drug resistance and helps to explain the biologic behavior of epithelial ovarian cancer as well as the usefulness of flow cytometry in predicting response to therapy, progression-free interval, and overall survival in this disease.

We concur with investigators such as Wils et al.,[10] who suggest that the results of flow cytometry be used in

conjunction with other prognosticators, such as clinical stage, to tailor treatment protocols based on risk assessment. This may be useful for two groups of patients, particularly those with favorable prognostic variables, to avoid unnecessary treatment morbidity, and those with an especially poor prognosis to target for investigational or no therapy.

Discussion

Dr. Christopher J. Jolles, Salt Lake City, Utah. The flow cytometer has become an important research tool in clinical oncology since the instrument became readily available 5 to 7 years ago. This complex device has provided some of our first insights into the cellular heterogeneity of tumors. To perform this procedure, an appropriately prepared and labeled cell suspension is analyzed to generate a histogram of single-cell label intensity. Although many different cellular components may be labeled, the initial clinical articles in this field focused on individual cellular DNA content. This enables the cytometrist to determine the fraction of tumor cells in each phase of the cell cycle and the fraction of cells with aneuploid chromosomes. Last year, Kallioniemi et al.[1] and Klemi et al.[2] reported series of 157 ovarian tumors showing correlation between increased nuclear aneuploidy, increased histologic nuclear grade, and decreased patient survival.

The authors are to be congratulated for their work in an area that is in the forefront of oncologic research. They have investigated their hypothesis that abnormal DNA flow cytometry is correlated with known poor prognostic factors in ovarian cancer. Tumor grade is perhaps the most important known pathologic prognostic feature in this disease. Unfortunately, they indicated that they were not able to demonstrate a correlation between aneupoidy and tumor grade. They attributed this result to the small number of patients in their report. As pointed out by Klemi et al.,[2] the term "aneuploid" has been defined in many ways by different flow cytometrists. The difficulty in defining a spectrum of clinical behavior may relate to the fact that >10% of benign cysts are also noted to be "aneuploid" by this technique and 93% of all malignant tumors in the authors' series were aneuploid. The authors did not define the formula used to calculate the "DNA index" in their article. It would be important to know if their index of aneuploidy was designed to weigh all cellular DNA contents equally or if increased weight was given to more severely aberrant cell populations and decreased weight given to near diploid cell populations. Indeed, this may explain the lack of correlation with tumor grade.

To ensure that tumor measurements accurately reflect aneuploidy, it is important to control for many potential sources of error. For example, falsely elevated DNA index results can be obtained when flow cytometry is performed on ovarian cancer metastases instead of primary tumors.[3] Although the authors used

ribonuclease treatment to decrease fluorescent interference from the increased ribonucleic acid content of tumor cells, additional control of this variable can be obtained by restricting analysis to nuclear suspensions. The expanded "S-phase" population of tumor cells can also cause false-positive results and this can be controlled by in vitro labeling of fresh tissue with radiothymidine and by accepting only sharp and well-defined G_0/G_1 peaks rather than broad-based background fluorescence in the range of 1.0 to 2.0. In contrast, falsely decreased DNA index results commonly occur when specimens are not controlled for their variable content of normal supporting mesothelial and connective tissue cells. This is commonly performed by gradient centrifugation of disaggregated cells before cell sorting. If this separation is not done, cell sorter results may reflect connective tissue content and thereby mask correlation between aneupoidy and tumor grade.

When the many variables are controlled, flow cytometry will add greatly to our understanding of cancer. Cytometric testing is presently in clinical application in many community-based hospitals throughout the country. When new technology is applied, it is important to determine how it is best used to modify our treatment approach. I am not aware of the evidence referred to by the authors that flow cytometry is more sensitive than histopathologic analysis in the detection of cancer, and I do not understand how this test can be used to define a tumor stage. On the basis of data presented and in view of these multiple experimental variables, I would ask the authors in what specific instances a determination of tumor aneuploidy should influence current patient management.

DR. JOHN R. DAVIS, Tucson, Arizona. For those in the audience unfamiliar with flow cytometry methods, a point of clarification is appropriate. Tissue blocks were selected for flow cytometry methodology analysis based on totality of tumor involvement in the sample. However, all aneuploid cases were defined on the basis of the presence of two G_0/G_1 peaks. One is the aneuploid clone; the other is normal host tissue from connective tissue, perhaps with an inflammatory component. The ubiquity of normal cells is important because an internal normal control is automatically available.

This article fulfilled its goals in terms of testing DNA features in epithelial ovarian cancer by flow cytometry with regard to survival and time to recurrence. For the latter, flow cytometry data were not as useful in prediction as were clinical data of stage and largest metastasis. The flow cytometry data do aid in survival prediction in terms of S-phase fraction and whether tumor is diploid or aneuploid. Prior literature findings were confirmed.

Is aneuploidy or diploidy more important than numerical value of DNA index? Although controversial in cases of cervical cancer,[1] ploidy in this article had greater value than DNA index.

Should flow cytometry be routine in ovarian carcinoma study? The authors suggest its use in conjunction with accepted prognostic factors for stratifying favorable or unfavorable outcomes. In breast[2] and lung[3] neoplasia, a major flow cytometry role is in early-stage neoplasms (small size and lymph node negative). Abnormal DNA content serves to predict outcome and a basis for management strategies.

Perhaps this will be the eventual role of flow cytometry in ovarian cancer. Patients with early-stage and low-grade carcinomas may be better subjects for routine flow cytometry than the entire group (with mostly late-stage and mid- to high-grade tumors).

I have several questions for Dr. Barnabei. (1) In selection of paraffinized tissue for flow cytometry analysis, was the whole block used or a 50 μm slice? (2) The initial draft of the article consisted of 30 μm cases, 28 of which were aneuploid. In the final draft an additional 31 cases were included, 20 of which were aneuploid. Aneuploid rates in the two sets were 93% and 65%, respectively. Were case acquisitions consecutive or selected for better balance in range?

DR. MURRAY J. CASEY, Omaha, Nebraska. I do not want to take the time of a formal discussion, but in experimental tumors the labeling index is considered to be a measure of the S phase, which in turn is the proportion of cells undergoing proliferation. In experimental mouse tumors, metastatic rate has been shown to be related to the proliferation rate.

For clinicians tumor grade has been a disappointing method of predicting whether or not the tumor would metastasize and a poor measure of the clinical outcome. We have had to rely on such crude measures as size of tumor, adhesions, spillage, external excrescences, etc. to prognosticate outcome. Flow cytometry and labeling now allow us to look at fresh tumors and assess the proportion of cells in the S phase. I would suggest to the authors that as a step in this direction, they restudy

the stage I tumors and determine the proportion of each tumor that was in the S phase, and determine if there is a correlation with the crude clinical findings reported on the operative report and the clinical outcome of those cases.

If, in fact, there was a direct correlation, then I believe that clinical laboratories would be prompt to adopt flow cytometry and the determination of labeling index, for instance, as a measure of determining whether or not patients with stage I tumors should or should not receive chemotherapy.

Dr. Eduard Eichner, Cleveland, Ohio. In the 1940s and 1950s I did lymphatic studies on these types of cases. One point of interest in our preliminary work of learning the size of material was the dye we used. We took different sizes of the dye to inject into the ovary and other organs and found that the real microsize, a millimeter or less, of the dye material went into the lymph nodes and then through the veins directly into the general circulation, which means that the small cell that is probably rapidly growing will spread fast.

The larger lumps of dye reached the node and stopped there, blocked the lymphatics, and then went backward. This type of study was reported then, so its use is a possibility.

Dr. Robert Carpenter, Houston, Texas. I have only limited knowledge of flow cytometry. If live tissue is compared with paraffin-embedded tissue, what is the sensitivity and specificity of the outcome? Will it have similar percentages, peaks, etc., or will there be a significant loss? If there is loss, will that then correlate with what you were addressing in your initial question?

Dr. Barnabei (Closing). Dr. Jolles was very precise; I was afraid somebody was going to ask me to extrapolate more on tumor grade. I think that is where the interest in some of this research lies.

I would like to comment on the correlation of aneuploidy and grade. As Dr. Weiland mentioned in a previous discussion, morphometry does not equal function. We have been very dependent on grade for a prognosis in such patients, and I think that grade may only be the large picture. We are gradually honing in on smaller aspects, and now we are studying content. As most of you know, we are also examining the gene level, oncogene expression, and those types of factors. We are getting more detailed in the ability to predict the outcome in these patients by utilizing factors other than tumor grade.

In almost all studies on ovarian cancer, when studied in multivariate analysis, grade becomes nonsignificant compared with other factors, including S-phase fraction and other aspects of flow cytometry.

Dr. Davis answered most of Dr. Jolles' questions about management, and I concur with what Dr. Casey said; perhaps the most useful aspect of flow cytometry at this point may be for analysis of early-stage cancers with low DNA content and low S-phase fraction to avoid significant morbidity in overzealous treatment.

I believe we did use nuclei and not cell suspensions for this study. The coefficient of variability for the DNA peaks ranged from 1 to about 6; peaks with a variability >7.5 were excluded.

In the studies I have seen on ovarian cancer, the aneuploidy percentage in fresh tissue is less than that found in paraffin-embedded tissue, although the peaks are actually clearer. The coefficient of variability is better, but there is a decreased percentage of aneuploidy. That is why I think our process of choosing tumors on the basis of their high tumor density is more indicative of the amount of aneuploidy in these tumor cells.

Finally, I think that until we are more successful in identification of patients with ovarian cancer before their disease is advanced, we must use whatever other information is available to improve survival in these women. I think the application of DNA flow cytometry will have clinical usefulness in the future for the evaluation and treatment of patients with epithelial ovarian cancer.

The Green Bay cesarean section study

I. The physician factor as a determinant of cesarean birth rates

Robert K. DeMott, MD, and Herbert F. Sandmire, MD
Green Bay, Wisconsin

This study was designed to identify the determinants of cesarean birth rates. The study population included all 1030 cesarean deliveries performed on singleton pregnancies by 11 obstetricians practicing at two Green Bay hospitals from 1986 through 1988; 1076 control patients with vaginal deliveries were selected for comparison purposes. The 1030 cesarean deliveries represented 14% of the 7335 singleton deliveries that occurred during the study period. Individual physician cesarean rates ranged from 5.6% to 19.7%. Cesarean rates for physician groups ranged from 9.8% to 18%. The variances in cesarean rates among individual and groups of physicians were not attributable to patient obstetric risk factors, socioeconomic status, service status, or duration of the physician's practice. Higher cesarean rates did not result in better neonatal outcome. Individual physician practice style was the only apparent determinant of cesarean rates for the 11 obstetricians. Current cesarean rates can be substantially reduced without sacrificing fetal and newborn safety. (AM J OBSTET GYNECOL 1990;162:1593-602.)

Key words: Cesarean birth rates, cesarean birth morbidity, physician factor as a determinant of cesarean rates

During the past 15 to 20 years cesarean section rates in the United States have increased from approximately 5% in the late 1960s to more than 25% in 1988.[1] Various factors explain this increase, reasons that usually are based on presumed improvement of neonatal outcomes without offsetting increased maternal morbidity and mortality. Interestingly, some centers have achieved similar reductions in perinatal mortality without dramatic increases in cesarean section rates or with rates substantially below those generally existing in the United States.[2, 3]

Proponents of increased cesarean rates have cited safety of the operation as a result of medical and surgical advances since the late 1960s and early 1970s. Nevertheless, we are unaware of any advances that resulted in increased cesarean section safety in the 1980s compared with the earlier period. Some authors consider present cesarean rates inappropriately high.[1, 3-7] Some have cited the individual practice style of the obstetrician as a strong determinant of cesarean rates.[8] Although we agree that the rates are high, we do not know *what* rate is optimal. Thus we designed this study to examine factors that influence route of delivery decisions, and the effect of the delivery route on maternal and newborn outcomes. Our study design permits us to evaluate not only individual practice differences, but also other variables that influence the choice of delivery route. The data will be further analyzed in relation to specific pregnancy and labor characteristics that influence route of delivery in the following complications: failure to progress, breech presentation, and fetal distress. These data will be the subject of future articles.

Material and methods

The study population included all singleton cesarean deliveries performed on private patients* by 11 board-certified obstetrician-gynecologists who practiced exclusively and full-time (over 400 deliveries) at two Green Bay hospitals from 1986 through 1988. Control patients with vaginal deliveries consisted of the next singleton vaginal delivery for that obstetrician after the index cesarean delivery. The total number of singleton deliveries was 7335; there were 1030 cesarean sections (14%). Those 1030 cesarean section and 1076† control patients' records were reviewed by labor and delivery nurses who recorded pertinent findings on data re-

*All Green Bay obstetric patients have private status, regardless of insurance or Medicaid status.

†After initial data collection, twin and triplet gestations were excluded from this study analysis. This resulted in slightly more control patients (vaginal deliveries) than cesarean deliveries in this singleton study. Because of the random nature of selection, no efforts were made to equalize the numbers in each study group.

trieval sheets. Similarly, the nurses reviewed all newborn records, except neonatal intensive care unit admissions; neonatal intensive care unit patient records were reviewed by the authors. Because of the small numbers of certain morbidities for newborn infants delivered by any single obstetrician (such as neonatal intensive care unit admissions), we elected to group the 11 physicians into low, middle, and high groups based on cesarean section rates. The assignment of the physicians to different cesarean rate groups was somewhat arbitrary but did result in all groups having a large number of deliveries.

One of the two hospitals in the study serves as the perinatal referral center for 13 surrounding northeastern Wisconsin and upper Michigan counties. A neonatologist attends all cesarean and selected vaginal deliveries, depending on the anticipated needs of the neonate. Because the 11 obstetricians in the study are consultants for that center and rotate as the on-call consultant for equal time periods, patient characteristics should not differ significantly among the physicians. Despite this, we analyzed those characteristics that have been reported to influence cesarean rates and neonatal outcomes for variations among individual physicians, groups of physicians, and cesarean versus vaginal delivery.[3, 8] Maternal age, parity, race, socioeconomic status, service status, insurance status, and county of residence failed to demonstrate significant differences in patient profiles. In addition, mean gestational age at delivery and mean birth weights did not significantly vary among physicians. Low- and high-birth-weight distribution also was uniformly distributed among physicians and physician groups. There was no difference in the mean number of years in practice in comparison of the low and high physician cesarean rate groups (low, 13%; middle, 20%; high, 13.5%). Continuous electronic fetal monitoring was used in a very high percentage of the laboring patients in the study and did not vary in frequency of use among individual physicians and physician groups.

We analyzed the data with PROC FREQ and PROC GLM programs in the SAS package. Relevant continuous variables such as infant weight or Apgar scores were subjected to two-way analysis of variance to examine interaction between physician groups and mode of delivery. For example, we asked whether the mean Apgar score for infants delivered by cesarean section differed from the mean score for vaginal deliveries by the same amount for all groups of physicians. In general, it did differ by the same amount for all the variables examined. When the data represented as frequencies (for example, frequencies of very large and very small babies), two-way tables of frequencies were analyzed with χ^2 to determine if physician groups differed in the percentages of very-low-birth-weight or macrosomic infants, with separate analyses for cesarean and vaginal delivery. We found no relationships between relevant variables and physician groups.

Results

Individual physician cesarean rates range from a low of 5.6% to a high of 19.7%. The mean rate for the entire study population was 14.0% (Table I).

Table II demonstrates the mean total, primary, and repeat cesarean rate for singleton pregnancies for the three groups of physicians. The total range was 9.8% to 18.0%. There are statistically significant increases in both the rates of primary and repeat cesarean sections when the high and low physician rate groups are compared.

Table III demonstrates the primary cesarean rate for singleton pregnancies for the three physician groups. For all indications combined, the difference between the high and low physician rate groups was statistically significant. Similarly, the high group performed significantly more cesarean sections for each individual indication. The distribution of cesarean section indications was similar for each physician and each physician group. For example, no one physician group had a disproportionately larger number of breech presentations or repeat cesarean sections (Table IV). One hundred thirty-two of the 1030 (12.8%) patients with cesarean deliveries and 119 of the 1076 patients (11.1%) with vaginal births had their health care costs paid by Medicaid; this difference was not statistically significant ($\chi^2 = 1.53$).

Neonatal outcome. Analysis of neonatal outcome included both the method of delivery and cesarean rate. There were no differences in the proportion of low Apgar scores, for vaginal and cesarean deliveries combined, among the different physician groups (Table V). When score were averaged over all physician groups, 1-minute Apgar scores were 0.5 units lower (7.39 vs 7.89) for infants delivered by cesarean versus vaginal delivery. The difference was 0.27 units lower (8.75 vs 9.02) for the 5-minute Apgar score. The fact that the interaction analysis of Apgar scores between cesarean and vaginal delivery failed to achieve statistical significance indicated that the differences were constant over the three physician groups.

The immediate need for neonatal resuscitation, by bag and mask or intubation, did not differ between physician groups for either cesarean or vaginal delivery (Table VI). One hundred eighty-seven infants (9%) in our study population of 2106 singleton deliveries were admitted to the neonatal intensive care unit (Table VI); 136 of these admissions followed cesarean delivery. For infants delivered by cesarean section, admission to the neonatal intensive care unit occurred slightly more frequently in the low cesarean rate group of physicians, but the difference is not statistically significant. A comparison of median length of stay in the neonatal intensive care unit suggests no effect of either mode of delivery or physician group (Table VI).

Length of respirator use was the same for all three physician groups (Table VI). When low-birth-weight infants were excluded from analysis, transient tachypnea ("wet lung") occurred 4.5 times more frequently after cesarean section compared with vaginal birth (41 cases versus 9). All five infants with birth weights >4500 gm who were admitted to the neonatal intensive care unit were delivered by cesarean section. Neonatal seizures, respiratory distress syndrome, apnea, intraventricular hemorrhage, pneumonia, sepsis, meconium aspiration syndrome, hypocalcemia, hypoglycemia, hyperbilirubinemia, wet lung, and death occurring primarily to infants admitted to the neonatal intensive care unit, either occurred too infrequently to statistically analyze or occurred with equal proportion in all groups of physicians regardless of cesarean rate (Table VII).

There were 17 neonatal deaths (8.1 per 1000) and five stillborn deliveries (2.4 per 1000) in the study population. This compares favorably with our overall perinatal mortality rate of 9.2 per 1000 infant births at the two study hospitals in the 3-year study period (60 neonatal deaths, 31 stillbirths, 9848 infant births over 20 weeks' gestation). Fourteen of the 17 infants who died and one of the 5 stillborn infants were delivered by cesarean section.

Of the 17 neonatal deaths, four occurred in infants with hypoplastic lungs (usually associated with prolonged rupture of membranes), five showed signs of Potter's syndrome, two had other congenital defects

Table II. Cesarean section rates for all singleton deliveries (N = 7335)*

	Physician group		
	Low	*Mid*	*High*
Total deliveries	2441	1972	2922
Category (% of all deliveries)			
Primary†	6.7	9.0	10.9

	100	100	100
Total cesarean section Rate (%)	9.8	13.4	18.0

incompatible with life, four died of severe prematurity, and two died of complications as a result of placental abruptio and sepsis, respectively. Eight of the 17 pregnant women whose infants died were transferred to our perinatal center from outlying communities on the suspicion of adverse perinatal outcome.

Maternal outcome. The incidence of spontaneous vaginal delivery was 93%. There were no significant differences in the low rate of either forceps or vacuum-assisted deliveries between any of the physician groups. Postpartum complications were also low in our study population. Cesarean deliveries were complicated by endometritis in only 1.8% of cases. Hemorrhage requiring transfusion and unexplained febrile illness (100.4° F occurring twice after the first postpartum day) occurred in 1.9% and 2.2% of cases, respectively. Overall, 84% of cesarean cases had no complications (major or minor). There were no statistically significant differences in the rates of these complications among physician groups.

As expected, vaginal deliveries resulted in very low rates of complications. For example, there was only one case of endometritis among women with vaginal deliveries. After vaginal deliveries hemorrhage occurred in only 1.6% of cases. Overall, 96% of women with vaginal deliveries reported no complications.

Comment

These results indicate that the major determinant of route of delivery is the individual practice style of each physician. The variances in cesarean rates among individuals and groups of physicians are not attributable to patient obstetric risk factors, socioeconomic status, service status, or duration of the physician's practice.

Contrary to a recent report by Gould et al.,[9] a higher proportion of poor patients in out study (Medicaid) had cesarean sections than the more affluent patients, although the difference is not significant. Gould et al. indicated that their observed differences in cesarean rates "may reflect the different settings (service status) in which the rich and poor receive their obstetrical care. The poor are more likely to give birth in public hospitals and have their health care costs covered by Medicaid, and are less likely to have private physicians." The results of our study demonstrate that the socioeconomic status of the patient is not a determinant of cesarean section rates. It is probable that the lower cesarean rate for poor patients reported by Gould et al. is a result of the individual physician factor associated with the differences in health care settings in which the rich and poor receive their obstetric care. Thus the lower socioeconomic status serves as a proxy for the difference in health care setting as a cause for lower cesarean rates.

The overall cesarean rate (14%) in our study population is below U.S. rates (25%) for the study period. This reduces the magnitude of possible differences in cesarean rates between low and high individual physicians and groups of physicians. For example, Goyert et al.[8] reported a range of 19.1% to 42.3% (mean, 26.9%) among 11 physicians, a difference of 23.2%. The individual physician range in our study was 5.6% to 19.7%, a difference of only 14.1%.

Some researchers have offered improved neonatal outcomes as justification for the fivefold increase in cesarean rates that have occurred during the past 15 to 20 years. Our data generally indicate less favorable newborn outcomes with cesarean compared with vaginal deliveries. This was particularly noted in the frequency of "wet lung" syndrome in term infants (4.5-fold increase). However, because cesarean deliveries occur more frequently in pregnancies with greater newborn risks (very low and very high birth weights), less favorable outcomes would be expected.

The main focus of this study was to determine the effect of cesarean rates on neonatal outcome when neonates from both cesarean and vaginal births were considered. Do newborns delivered by physicians with high cesarean rates fare better than newborns delivered by physicians with low cesarean rates? Our data clearly demonstrate no difference in the condition of newborn infants from cesarean and vaginal births comparing low to high cesarean rate physician groups (Tables V, VI, and VII). Therefore the physicians with low cesarean rates do not place infants at greater risk by the avoidance of many cesarean sections in their patient population. Other authors have reported similar findings.[2, 3, 8]

The fear of professional liability claims produces a substantial impact on delivery decisions.[10, 11] Most of the 11 physicians have had one or more liability claims filed against them. For the younger physicians who have not,

they are acutely aware of past and pending claims against their partners.

The major legal threat to obstetricians is the allegation of failure to perform or delay in performance of cesarean sections. The infant's later cerebral palsy is attributed to asphyxia or trauma resulting from the alleged failures of the physician. The three major indicators—failure to progress, breech presentation,

and fetal distress—for primary cesarean section fall within this "legal risk" group.

Although all the physicians in our study have an equal awareness of the legal risks of delivering infants, it appears that the physicians with high cesarean rates are influenced by the risk to a greater degree than those with low rates. Their proportionate increase for all "legal risk" cesarean indications is supportive of this conclusion. Furthermore, two of the three physicians in our study who routinely obtain umbilical arterial blood gas studies on newborn infants are in the high cesarean rate group. This also suggests a higher sensitivity to legal risks since the sole purpose of routine performance of the test is the belief that it offers protection against liability claims. The authors do not share the latter belief.

The physicians with "high" cesarean rates in our study had substantially lower rates than those nationally reported (18% vs 25%) during the study period and lower than the physician with the lowest cesarean rate in the study by Goyert et al.[8] This occurred even though one of the two hospitals serves as a regional perinatal center. Therefore legal pressures were much more effectively resisted by these doctors than their national colleagues.[1]

With the waning of maternal morbidity in the early 1970s, the obstetric discipline concentrated on the reduction of newborn and infant morbidity. Considerable excitement ensued over the prospects of preventing intrapartum fetal "brain damage" and subsequent cerebral palsy. This resulted in a sharp increase in cesarean rates to protect the fetus from the "hostile" intrauterine environment or "traumatic delivery" with expected consequent prevention of newborn and infant neurologic impairment. Unfortunately, the anticipated benefits have not materialized. Cerebral palsy is neither prevented by appropriate obstetric response to asphyxial electronic fetal monitor patterns,[12] nor caused by a delayed response to similar changes.[13] Profound intrapartum asphyxia associated with many of 324 cases of umbilical cord prolapse did not increase the risk of later cerebral palsy in the infants who experienced that complication.[14] In recent findings related to acid-base status at birth and neurodevelopmental outcome at 4½ years, Dennis et al.[15] reported "the highest proportion of unimpaired children was found among those who were most severely acidotic at birth (pH 7.04; 2 below mean)." Cerebral palsy is not caused by prolonged labor, intrapartum asphyxia, or vaginal breech delivery[14, 16]; yet the obstetrician is blamed when it occurs in association with those conditions. This information has been available to the obstetric discipline since the publication by Nelson and Ellenberg[14] in 1984, entitled "Obstetric Complications as Risk Factors for Cerebral Palsy or Seizure Disorders." Among the population with cerebral palsy the following obstetric complications were not overrepresented: cord prolapse (0.3), fetal heart rate <100 beats/min (0.4), oxytocin augmentation (0.3), middle or high use of forceps (0.4), and second stage of labor longer than 59 minutes (0.3) compared with obstetric patients with no complications (0.3). The same authors reported no elevated risk for cerebral palsy when vaginal and cesarean breech deliveries were compared.[16]

We do not know, and the data from this study do not indicate, the optimal cesarean section rate. Quilligan[17] has suggested 8% and Porreco[3] has achieved a personal cesarean delivery rate of 6%. The combined rate for the two physicians with the lowest cesarean rates in our study was 7.8%. The neonatal outcome for these physicians is as good as that for the two physicians with high (19.6%) cesarean rates. Although our data do not conclusively identify an optimal cesarean section rate, the rate of the two lowest physicians is within the range suggested by Quilligan[17] and achieved by Porreco.[3]

Having identified the individual physician factor as a determinant of cesarean rate, we currently are identifying variations of patient management for the three major indicators of cesarean section—failure to progress, breech presentation, and presumed fetal distress. When physicians with high and low cesarean rates are compared for failure to progress, we are tabulating the following: parity, birth weight, gestational age, labor disorders, oxytocin dose, and duration for both induction and augmentation, use of intrauterine pressure catheter, cervical dilation at time of cesarean, use or nonuse of epidural anesthesia, trial of forceps or vacuum, variations in time of day (or night) of cesarean births plus all the individual patient characteristics analyzed in this article including neonatal outcome. Similarly, appropriate detailed analyses will be performed for breech and fetal distress cesarean births. The information obtained may be useful in the development of strategies to safely lower the cesarean rate.

Individual practice style is the only identifiable determinant of different cesarean rates for the 11 obstetricians in this study. In our opinion, the variation in individual rates is a result of the variation in physicians' reactions to current obstetric legal risks. Current cesarean rates can be substantially reduced without sacrificing fetal and newborn safety. This is unlikely to happen until medical-legal proceedings accord greater weight to sound scientific information.[11]

We thank the obstetric nurses at Bellin Memorial and St. Vincent Hospitals for their detailed record review and data collection; Vicki Sibilsky, our research assistant; and Professor David Jowett of the University of Wisconsin at Green Bay for his statistical analysis.

Discussion

DR. STEPHEN A. MYERS, Chicago, Illinois. An increasing number of obstetricians agree with Drs. DeMott and Sandmire when they state that "current cesarean rates can be substantially reduced without sacrificing fetal and newborn safety." Congratulations are in order to those 11 obstetricians who were surveyed in this report and who, over the 3-year period in over 7000 deliveries, had only a collective cesarean rate of 14%. This is similar to the 11½ % cesarean section rate we reported last year for Mount Sinai Hospital Medical Center in Chicago, which has now been maintained for almost 4 years. As more studies are reported, we hopefully will be able to refine our understanding of indications for the procedure and perhaps curtail its performance when no benefit can be established for the operation. The Green Bay data demonstrate wide variations among individuals in determining route of delivery. The individual cesarean rates differed by a factor of 3, ranging from 6% to 20%. Wide personal variations in cesarean rates also prevail in hospitals with much higher overall rates. In such a context, the "physician factor" warrants scrutiny. However, instead of suggesting what may account for those differences, the authors have only tabulated them. Moreover, discussion of cerebral palsy and malpractice concerns, although possibly relevant to the issue, are not addressed.

The authors' working hypothesis is that individual physician factors account for variations in cesarean rates, not medical-obstetric differences in either populations or indications. Several recent publications already recognize this fact.[1, 2] These data merely repeat the same observation without any analysis as to why it is so.

Several methodologic concerns arise; there are errors in the tables. There are several examples of different numbers for the same data from table to table, i.e., Table II "high" primary rate = 11% compared with Table III "high" primary = 11.8%. Many such errors raise serious questions about accuracy and methodology of the data collection and analysis.) The low-mid-high groupings are entirely arbitrary, apparently to divide the 11 practitioners as equally as possible. However, within the low group the range is 5.6% to 11.8% (a factor of 2), whereas in the mid group the range is 12.7% to 13.8%, an unnoticeable difference. The outcome data refer only to Apgar scores. Moreover, twice as many low 1-minute scores are in the "low" cesarean group compared with the "high" cesarean group (4.3% [Apgar score of 1 to 6] versus 2.1%, $p < 0.05$). Too little analysis of this difference is made in this paper. One has to wonder whether such a restricted evaluation of outcome is adequate.

However, the basic question remains: *what* physician factors account for individual differences in cesarean rates? To answer this important question, others have to be asked and answered. For example: (1) How many patients have had more than one previous cesarean section? How many of these were allowed a trial of labor? (2) What are the individuals' vaginal birth rates after previous cesareans sections? What are their vaginal breech delivery rates? (3) What are the average birth weights of infants delivered by cesarean section for dystocia? What proportion have birth weights <3000 gm? (4) How often is conduction anesthesia or oxytocin used?

Similarly, a more direct assessment of individual malpractice perception and experience could support the authors' proposition that "the variation in individual rates is a result of the variation in physicians' reactions to obstetric legal risks." The following questions are

raised. (1) Which of the 11 physicians were sued? What were the allegations? (2) Would route of delivery have made a difference? (3) Was the suit settled or did it proceed to jury award? (4) Were adverse outcomes experienced in the absence of legal action? (5) Did any case of cerebral palsy occur during this study?

That individual perceptions can influence cesarean section rates is, in fact, quite well demonstrated by these data. With a collective cesarean rate of 14%, a lower cesarean rate was observed in infants weighing more than 4500 gm than in infants weighing <1500 gm (53 of 81 >4500 gm vs 34 of 41 <1500 gm; $\chi^2 = 4.14$; $p < 0.05$). An understanding of factors accounting for such observations, whether in Green Bay or Chicago, would serve our patients and our profession well.

Dr. Robert E. Wall, Denver, Colorado. The authors have provided a retrospective review of all singleton cesarean deliveries performed by 11 board-certified obstetricians from 1986 through 1988. Their stated objectives were: (1) to examine factors that influence route of delivery decisions and (2) to examine the effect of the delivery route on maternal and newborn outcomes.

In their study design the authors compared all cesarean deliveries with the next single vaginal delivery for a given practitioner following each of the index cesarean deliveries. Arbitrarily, all cesarean deliveries for multiple gestations were excluded from the cesarean group without eliminating the corresponding vaginal delivery from the vaginal delivery group. Although not an optimal design, the impact on their results was probably small.

The 11 physicians were divided into three study groups based on cesarean delivery rate. What factors determined how many physician groups were compared? Why was physician no. 4, whose cesarean rate was 11.8%, included in the low cesarean rate group with physician no. 1, whose cesarean rate was only 5.6%? Furthermore, why was physician no. 5, whose rate was 12.7%, included in the middle cesarean rate group, rather than with physician no. 4 at 11.8%? The rationale behind the construction of these physician groups remains unclear.

In determining the results, only *scheduled* repeat cesarean deliveries were included in the *repeat* cesarean rate. Patients who underwent a second cesarean delivery, despite a trial of labor, were included in the *primary* cesarean group. Although many obstetricians now allow a trial of labor, some are unwilling to use interventions such as epidural anesthesia, oxytocin augmentation, or induction of labor that will allow maximum chance for successful vaginal births after cesarean section. They frequently "bail out" early in labor without an adequate trial. Should we also include these so called vaginal births after cesarean section failures as primary cesareans?

In their results the authors also stated, "Our data clearly demonstrate no difference in the condition of newborn infants . . . comparing low to high rate physician groups." However, comparison of neonatal outcome between the low and high cesarean rate physician groups included only (1) Apgar scores, (2) the need for neonatal resuscitation, and (3) admission to and length of stay in the neonatal intensive care unit. Umbilical artery blood gas determination, neonatal sepsis, intraventricular hemorrhage, apnea and bradycardia in the nursery, neonatal seizure activity, neonatal mortality, and later childhood developmental delays were not or could not be compared between low and high cesarean rate physician groups. Without additional data, I do not believe the authors can claim to "clearly demonstrate no difference in the condition of newborn infants . . . comparing low to high cesarean rate physician groups."

The incidence of maternal complications reported was low in both vaginal delivery and cesarean delivery groups. It is not possible to determine the numbers of each maternal complication reported, nor their distribution among physician groups. The authors reported an incidence of postcesarean endometritis of <1.8%. What was their definition of endometritis?

Given the very low incidence of individual complications in each physician group, were there really "no statistically significant differences in the rates of these complications among physician groups"? The authors should subject their evaluation to statistical power analysis to be certain their conclusion is valid. Would other parameters indicative of maternal outcome, such as wound infection rate, length of hospital stay, and cost of hospitalization, provide additional comparisons between low and high rate physician groups?

The authors compared the morbidity of *all* newborns and mothers delivered by cesarean sections with *all* those delivered vaginally, regardless of physician group. However, no rational comparisons can be made based solely on route of delivery. Preexisting maternal and fetal compromise themselves are often the major determinants of delivery route.

Finally, the authors concluded that "the major determinant of route of delivery is the individual practice style of each physician." I generally agree with this assessment. However, they further stated, "the variation in individual rates is a result of the variation in physicians' reactions to current obstetric legal risks." They provided no data regarding other very important intrapartum practice styles that could explain the marked variation in individual cesarean rates. These variables include (1) the use of intrauterine pressure monitoring

to adequately document "failure to progress," (2) the use of external cephalic version to avoid cesarean breech delivery, (3) the use of fetal scalp pH determination or intraamniotic saline solution infusion to evaluate and treat "fetal distress," and (4) the use of epidural and caudal anesthesia in labor, and its effect on the progress of labor. Could variations in any or all of these factors also explain the marked variation in cesarean rates between individual physicians?

In summary, the authors and the entire physician group are to be commended for maintaining a cesarean rate well below the national average in the United States. Their mothers and newborn infants appear to have very low rates of complications after both vaginal and cesarean delivery. I agree that the fear of litigation has an effect on individual practice style. However, this study does not provide us with the data necessary to quantitate the role of current obstetric legal risks on a physician's individual practice style or cesarean rate. The authors omitted multiple variables that, in my opinion, substantially influence decisions concerning the route of delivery. The data presented are inadequate to accurately compare maternal and newborn outcomes between the low and high cesarean rate physician groups. If additional information can be supplied and if further analysis is conducted, I believe this study will be able to provide us with information regarding the impact of "fear of litigation" on an individual physician's cesarean rate. Any discrepancy in maternal and newborn outcome between the cesarean rate physician groups may then be evident. Finally, I would also be interested in knowing the individual cesarean rates of the authors during this study period.

Dr. Murray J. Casey, Omaha, Nebraska. Dr. Sandmire told me about this article a few weeks ago, so I have had a chance to think about it a while; although he did not tell me the specifics and I have not read it. I hope that Dr. Wall's unanswered questions are answered, but in thinking about the authors' findings, it gave me an opportunity to try to combine this with some of the other things that I know.

For many years researchers in business and management behavior have recognized that although there is a continuum of risk and risk avoidance characteristics in personality, to some extent this can be stratified. Researchers do not know how to deal with the categorization once it is defined. For instance, there seem to be no quantifiable factors that would predict who would be a better manager in a mature or in an emerging firm or who would be a better entrepreneur, etc. So the problem of who will react to certain agreed obstetric data by performing a cesarean section may reflect much more basic levels of individual personality than simply the fear of litigation.

Dr. Richard A. Hartman, St. Louis, Missouri. I have only one question. Did the individual workload of any one physician affect the cesarean rate? I think physician No. 1 had a total of about 500 deliveries. Physician No. 10 had almost 1200 in a 3-year time period.

Dr. Sidney F. Bottoms, Detroit, Michigan. I would like to compliment the authors. I recognize that there are many questions you can ask about a study in this area; however, it is literally impossible to study everything about labor and delivery all at once.

I think it is important to stop fooling ourselves and saying "Oh, well there might be some difference between these patients if you studied everything on God's earth and we start to deal with the issue because everybody who's had any experience in the delivery room knows that some people are going to go to the knife a whole lot faster than the others." I don't know anyone who would deny that.

If you think about your own day-to-day observations, you know that some doctors' patients are always more apt to have a cesarean section. I compliment the authors' forthrightness to start dealing with an important issue.

Dr. Jack W. Pearson, Tucson, Arizona. A few years ago I reported from Indiana University a 9-year experience on obstetric outcome in an indigent urban population with reference to cesarean section rate and associated perinatal mortality rate.[1] At that time we were challenging the belief that the increasing cesarean section rate was the cause of the decreasing perinatal mortality rate.

Our cesarean section rate over that period remained stable and remarkably close to what was reported today at the lower end of the spectrum: approximately an 8% *total* cesarean section rate. Over 3000 deliveries a year and a total of approximately 30,000 deliveries were analyzed.

During that same time, the perinatal mortality rate decreased 50%. On the basis of our findings, I would suggest that our improvement of perinatal outcome over the past 10 to 20 years may relate to the performance of cesarean section and other aspects of improved obstetric care. However, our experience would suggest that dramatic improvements in neonatal care have been a far more significant influence on our improving perinatal outcome.

REFERENCE

Dr. Paul C. Nehra, Detroit, Michigan. In some hospitals, especially community hospitals, there is an active family practice service, and family practitioners tend to refer patients to certain obstetricians more often than others. That may lead to a higher cesarean section rate for certain physicians in these community hospitals. I

do not think this has been addressed in any of the previous studies.

Did some of the physicians in this study have higher cesarean section rates potentially because they were the chosen referral physician?

Dr. Sandmire (Closing). The distribution of the groups was somewhat arbitrary. I do not think we could have distributed the data to satisfy everyone, but we did the distribution to have larger groups for statistical analysis. In other words, the morbidity is rather infrequent. We thought that instead of calculating morbidity and outcome measures for each individual obstetrician, we should use groups to give greater statistical power. We agree with the discussants that there is little difference in cesarean rates for the last physician in the low group and the first physician in the middle group. The same is true for the last and first physicians in groups two and three, respectively. Because our conclusions are based on outcomes comparing the low and high cesarean rate physician groups (where there is a substantial difference [9.8% vs 18.0%]), our groupings are appropriate.

Dr. Wall mentioned that we did not use enough different measures of outcomes to compare one group with the other. We did send multiple updated papers to the discussants; I hope he got the more recent ones. Although we did not include it on the tables, we did analyze all of the many different outcomes, including seizures in the newborn, sepsis, length of respirator use, and neonatal intensive care unit admissions and length of stay. He also mentioned the difference in Apgar scores between the high and low cesarean rate groups. We apologize that there was an error on Table V in an earlier draft. The corrected table demonstrates no difference in Apgar scores between the different physician groups.

With regard to the request for more information, this is our first study with this patient population. We will be providing at least three more articles, each reporting on a detailed analysis for the major indications for cesarean section. For example, in the failure to progress group, we will report the length of labor, the latent period, and the degree of cervical dilatation at the time of intervention by cesarean. In addition, the oxytocin dose and duration of use will be reported. The influence of birth weight on cesarean rate will be analyzed as well as use or nonuse of epidural anesthesia. We will provide all the information that was suggested. As Dr. Bottoms says, you can't deal with everything in a 12-minute paper or one article.

We have a relatively small community and every obstetrician has equal knowledge about the legal risks involved in practicing obstetrics. That will not be influenced by who was sued and who was not; practically speaking, almost all the physicians in the study group have been sued, some more than others; but for those few young physicians who have not, I tell them to be patient.

I think I commented on most of the things that Dr. Myers asked about.

There were some important questions by Dr. Wall regarding intrauterine pressure catheter use or nonuse, epidural anesthesia, cephalic version, breech presentation, and scalp pH. Those questions will be answered in our future articles, but I can tell you that epidural anesthesia is not used and that the intrauterine pressure monitor was used very infrequently. Those were not variables that differed from one obstetrician or group of obstetricians compared with the others.

Dr. Hartman asked if the individual physician workload affected the cesarean rate. Dr. DeMott, who is physician No. 1 in Table I, came to Green Bay about halfway through the study period and had only 408 deliveries. Obstetrician No. 8 was also present for only the last half of the study period. The reason we grouped the physicians is because 408 deliveries is not an adequate sample size. I am No. 4 on the table.

There was a comment that the data do not prove that it is as safe for the infants who are delivered by physicians with low cesarean rates. We believe that our data *do* demonstrate equal neonatal outcomes for physicians with both low and high cesarean rate. In addition, I think that obstetricians have worked themselves "into a hole" in which the burden of proof somehow has fallen on advocates of fewer operative deliveries, when in fact those who contend higher cesarean rates improve outcome are the ones who should have to present justifying data.

Dr. Nehra asked about family practice referrals. I do not believe that is a factor in cesarean rates because the physicians are grouped by cesarean rate rather than professional associations. In fact, physicians in the high group represent three different practices.

Our conclusion that medical-legal risks influence cesarean rates is somewhat inferential and based on the personal knowledge that we all make some decisions based on those risks. In addition, no other variable explaining different cesarean rates was identified.

We have not used the term *unnecessary* cesarean section. Every one of these cesarean sections was necessary. The obstetrician performing each cesarean had a reason to perform the cesarean. We are saying that perhaps some of those reasons for performing cesarean sections were not totally appropriate from the scientific standpoint but arise from legal pressure. If we are to solve a problem, then we have to be sure we know what the problem is; and I believe the cesarean section rate is higher than optimum, and I think the major contributor to that problem the legal pressure to which our discipline is subjected.

Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance

Robert P. Lorenz, MD,[a, c] Christine H. Comstock, MD,[a, c] Sidney F. Bottoms, MD,[b, c] and Sharon R. Marx, RNC, MS[a]

Royal Oak and Detroit, Michigan

This study was designed to compare the effectiveness of cervical assessment by either ultrasonography or bimanual pelvic examination in a program for preterm labor surveillance. Patients ($n = 57$) at risk for preterm birth were seen once a week for patient education, review of symptoms, and cervical evaluation. Cervical evaluation was assigned randomly to either ultrasonographic evaluation or pelvic examination. The groups did not differ in demographic or obstetric factors. The overall rate of prematurity was 18%. Preterm labor was more frequent with ultrasonographic evaluation (52%) than with pelvic examination (25%) ($p < 0.05$). The group evaluated by ultrasonography received oral tocolytic agents (55%) more than the group that had pelvic examinations (21%) ($p < 0.02$). The groups did not differ in infant birth weights, length of gestation, or neonatal mortality or morbidity. In this prospective randomized study of patients at risk for preterm birth, patients under surveillance by ultrasonographic assessment of the cervix did not fare better than those assigned to bimanual examination. (Am J Obstet Gynecol 1990;162:1603-10.)

Key words: Preterm birth prevention, ultrasonography, precocious cervical maturation, prematurity

Preterm birth remains a leading cause of infant mortality and morbidity in this country. Efforts to lower the rate of preterm birth have been successful with a combination of professional and lay education, risk assessment, patient education regarding warning signs of labor, and recommendations for limitation of physical activity,[1] close surveillance, and intervention for early preterm labor.[2] Although the physiology of the onset of normal and preterm labor is not well understood, there is considerable evidence that active preterm labor is often preceded by a period of increasing uterine activity and associated change in the cervix that may be relatively asymptomatic.

Assessment of the cervix, either in all prenatal patients, or in a subset of patients at increased risk, is an integral part of all programs for prevention of preterm birth. Bouyer et al.[3] identified precocious maturation of the cervix on physical examination as the strongest single risk factor for preterm birth in 7937 pregnancies. Herron et al.[2] reduced the rate of preterm birth in a program of risk assessment and targeted intense patient education, surveillance, and weekly bimanual pelvic examination. Papiernik et al.[4] advocated pelvic examination of all prenatal patients at each visit. Stubbs et al.[5] suggested that pelvic examination at 28 weeks in all pregnancies may reduce the incidence of preterm birth by identifying asymptomatic patients with preterm abnormal cervical change. Bouyer et al.[3] reported the normal range of pelvic examination for each gestational age, and the ability to predict risk of preterm birth on the basis of a single examination.

As ultrasonographic equipment and techniques have improved, imaging of the cervix and lower uterine segment has been recommended,[6] but there are technical difficulties.[7] O'Leary and Ferrell[8] described good correlation between the Bishop score on bimanual examination and an ultrasonographic score in 46 patients. Brown et al.[9] also demonstrated good correlation between digital examination and both transabdominal and transvaginal ultrasonography in 20 unselected patients. Ayers et al.[10] used ultrasonography in 88 patients with previous second-trimester losses and believed its use was beneficial. There has been no prospective study comparing ultrasonographic evaluation and bimanual assessment of the cervix for preterm birth prevention.

The purpose of this study was to compare in a prospective randomized fashion the effectiveness of cervical assessment by either ultrasonography or bimanual pelvic examination in a program for preterm labor surveillance.

Material and methods

Pregnant women of less than 34 weeks' gestation who were at risk for preterm birth were assessed by a risk scoring system.[11] Patients with a risk score of 10 or greater were offered participation in this study. Patients were excluded from entry into the study if they had already been treated for preterm labor during the current pregnancy with intravenous tocolytic agents, oral tocolytics, or emergency cerclage. This study was approved by the institutional human investigation committee and written informed consent was obtained.

Patients planning to be delivered of their infants at William Beaumont Hospital in Royal Oak, Michigan were enrolled in the study between July 1, 1985, and Aug. 31, 1988.

Patients were seen weekly at the hospital by one of the authors from 20 weeks' gestation (or at entry if enrolled after 20 weeks) until 37 weeks' gestation for patient education, review of symptoms, and cervical evaluation. Each patient education and symptom review visit was done by one of the authors and lasted 30 to 60 minutes. Routine prenatal care was continued by the primary physician, who was also responsible for intervention if surveillance demonstrated significant changes.

Patients were assigned by the use of random number table at the time of entry to a method for weekly cervical evaluation, either by bimanual pelvic examination ("pelvic group") or by transabdominal ultrasonographic examination ("ultrasonography group"). This cervical evaluation was done weekly in all patients. Patients assigned to the ultrasonography group who reported a change in symptoms consistent with increased uterine activity at the weekly surveillance visit would also undergo pelvic examination.

For ultrasonographic examination of the cervix, a sector transducer of a GE RT3000 (Milwaukee) or Acuson (Mountain View, Calif.) ultrasonographic scanner was used to measure cervical length in the supine position. The superior wall of the bladder was always perpendicular to the cephalocaudad axis to ensure an accurate, standardized study. If the bladder was too full, cervical length was falsely elongated; if it was not full enough, the length could not be measured. The length was measured from the internal os to the external os in the sagittal plane with the transabdominal approach. Visualization of the cervical canal was a requirement for measurement and reporting cervical length. The internal os is usually identified by a dimple in the uterine contour. If the dimple was not visualized, a line extending through the canal was extended to the interior uterine contour. If the external os was not visualized, the measurement was taken at the end of the visualized cervical canal. A significant change was identified if the cervix was shorter by ≥ 1 cm than the previous examination. This distance was chosen because there was often <1 cm of variation between examinations. Funneling of the cervix was noted but not considered abnormal unless other findings (e.g., shortening of the canal) were also observed. Dilatation of the canal was considered significant.

Patients were asked to increase fluid intake and not void before the study and then were asked to partially empty their bladders if the standard bladder image could not be obtained. Patients assigned to the ultrasonography group underwent a basic full study at the first visit (biparietal diameter and femur length[12]). Subsequent visits for assessment of the cervix were brief (5 to 10 minutes including adjustment of bladder volume).

The pelvic examination group had a bimanual examination and a modified Bishop score[13] weekly by one of the authors. Softening of the cervix from 34 to 37 weeks' gestation was considered normal; any other change in the Bishop score was considered significant.

The primary obstetrician was notified immediately if the ultrasonographic surveillance or pelvic examination showed a significant change.

Shortly after the study began, home ambulatory uterine monitoring became available and all patients enrolled thereafter underwent home monitoring (Tokos Medical Corp., Santa Ana, Calif.). When evidence of possible labor was identified during a weekly study visit (change on ultrasonographic evaluation or pelvic examination, marked increase in patient symptoms), the primary obstetrician was contacted by telephone for further management. This research study did not dictate or recommend further management. Further observations by standard tokodynamometry required hospital admission at our institution.

For purposes of this study, a patient was identified retrospectively as having preterm labor if she had any of the following before 37 completed weeks of gestation: (1) uterine contractions and progressive cervical dilatation resulting in preterm birth, or (2) frequent uterine contractions that were treated with hospitalization and initiation of or an increase in pharmacologic therapy, or (3) precocious cervical maturation that was treated with hospitalization and initiation of or an increase in pharmacologic therapy.

Patients with multiple gestations were enrolled in this study, randomized in the above described system, but will be reported separately.

Clinical characteristics of the two groups were analyzed by t test, χ^2 and Fisher's exact tests as appropriate. Survival analysis was used to compare the primary outcome measure, gestational age at delivery, between the two groups.[14] A value of $p \leq 0.05$ was considered significant.

Table I. Demographic and obstetric history by assigned group

	Method of surveillance		
	Pelvic examination	*Ultrasonography*	*Significance*
No. of patients	28	29	
Maternal age (yr, mean ± SD)	29.4 ± 4.5	27.0 ± 5.1	NS ($p < 0.06$)
Race, white, *n* (%)	28 (100%)	28 (97%)	NS*
Gravidity (mean ± SD)	3.9 ± 1.7	3.2 ± 1.8	NS
Previous term birth (mean ± SD)	0.4 ± 0.7	0.3 ± 0.6	NS
Previous preterm birth (mean ± SD)	1.1 ± 0.5	1.1 ± 0.8	NS
Abortions (mean ± SD)	1.4 ± 1.4	0.9 ± 1.4	NS
Living children (mean ± SD)	1.1 ± 0.7	1.0 ± 0.9	NS
Risk score (mean ± SD)	17.3 ± 6.8	20.8 ± 9.9	NS
Patient source, clinic, *n* (%)	8 (29%)	14 (48%)	NS

*Fisher's exact test (two-tailed).

Results

Fifty-nine patients with singleton pregnancies were enrolled. Two patients were removed from the study because they were delivered prematurely for unrelated reasons (severe intrauterine growth retardation at 34 weeks' gestation, abnormal fetal testing at 32 weeks' gestation in type I diabetes mellitus). The groups did not differ in number of previous preterm or term births, previous abortions, race, preterm risk score, primary physician source (private versus clinic), or use of home monitoring (Table I). There appeared to be a trend for the pelvic group to have an older maternal age than the ultrasonography group ($p < 0.06$). Management was not significantly different (Table II) with regard to the following: use of cerclage, intravenous tocolytic agents, use of betamethasone, number of predelivery admissions, or number of days in the hospital before delivery. The ultrasonography group did receive oral tocolytic agents more frequently ($p < 0.02$) than the pelvic group.

Dilatation of the cervical canal was not seen on ultrasonography without significant shortening of the length of the canal.

Pregnancy outcome in the two groups is shown in Table III. The overall rate of preterm delivery (<37 weeks' gestation) was 18%. The overall rate of preterm labor was 39%. Preterm labor was more frequent in the ultrasonography group (52%) than in the pelvic group (25%) ($p < 0.05$).

Life-table analysis of gestational age at delivery demonstrated a significant difference ($p < 0.05$).[15] No significant difference was found when all deliveries after 37 weeks' gestation were grouped as term deliveries (i.e., results censored after 37 weeks.)[16] Thus the primary difference between the groups was accounted for by the differences beyond 37 weeks' gestation.

Power analysis[17] indicated that this study had an 80% chance of detecting a 2.5-week prolongation of gestational age in the ultrasonography group at a value of $p < 0.05$.

Birth weights were similar in both groups, as were Apgar scores, neonatal hospital days, sepsis (none in either group), sex distribution, and neonatal complications. One newborn in each group died (infants with birth weights of 500 and 375 gm).

Because multiple outcome variables were studied without any observed benefit, the actual power of this study to identify a favorable benefit to ultrasonography is probably higher than 80%.

Comment

In this prospective randomized study of patients at risk for preterm birth who were followed in a program of preterm labor surveillance, patients followed by weekly ultrasonographic assessment of the cervix fared no better than those followed by weekly bimanual examination. The ultrasonography group had more cases of preterm labor ($p < 0.05$).

This is the first randomized prospective study comparing these two methods of assessment of the cervix, and demonstrates no apparent benefit to ultrasonographic surveillance. This finding differs from the observation of others.[10, 18]

Theoretically, ultrasonographic assessment of the cervix by transabdominal scanning has the advantages of less risk of ascending transvaginal infection, less risk of local prostaglandin release that is associated with bimanual examinations (Ferguson reflex), and better assessment of the internal os. Conversely, a bimanual examination with a Bishop score assesses factors that ultrasonography does not: consistency of the cervix, location in the vagina, and station of the presenting part.

The apparent difference in rates of preterm labor

†Fisher's exact test (two-tailed).

and use of oral tocolytic therapy in these comparable groups is unexplained. Possible explanations are: (1) The groups differ in some unidentified risk factor for preterm labor; (2) a chance observation that occurred randomly when in fact there is no difference (this explanation has a 4% probability); (3) ultrasonography provides a less effective tool for early intervention for treatment of cervical change; (4) ultrasonographic surveillance predisposes to preterm labor in some way. Of possible relevance to the latter is the clinical observation that bladder distention may increase uterine activity. Studies are currently underway that try to address these issues.

The precocious maturation of the cervix is a significant risk factor for preterm birth, the importance of which cannot be overstated. In a random examination during pregnancy by either ultrasonography or pelvic examination, such a finding warrants further evaluation. In a program of preterm birth prevention including weekly examination of the cervix, this study

demonstrates no advantage, and possible problems, with surveillance by ultrasonography rather than bimanual examination.

We acknowledge the contribution by Tokos Medical Corporation in providing home ambulatory tokodynamometry services.

Discussion

DR. RICK W. MARTIN, Jackson, Mississippi. The authors have evaluated the usefulness of ultrasonographic assessment of the cervix in the management of pregnant women at risk for preterm labor. Cervical dilatation has been observed to be a reliable predictor of preterm delivery as a component of formal prematurity prevention programs.[1] Cervical dilatation has been determined by ultrasonographic evaluation. Therefore it is reasonable, to determine the benefit from cervical evaluation by ultrasonography compared with bimanual examination. This is not the first article to deal with this modality, however it is the first to study its benefit in a randomized, prospective manner. Ultrasonography does allow evaluation of the internal cervical os when access is limited with the bimanual examination. Although difficulties, primarily concerning interpretation and the effects of bladder filling on cervical length have been reported, O'Leary and Ferrell[2] have shown correlation between an ultrasonographic cervical scoring system and the Bishop score. Transvaginal ultrasonography has been reported to offer slightly better imaging of the cervix than the abdominal approach.[3] This method would be particularly useful in the obese gravid woman. I would be interested in difficulties the authors encountered with the ultrasonographic examination. What factors affected the reliability of ultrasonographic measurement?

Table III indicates a significant difference in the number of women in each group who had preterm labor. This would not be expected since the groups were chosen at random. Although a standard risk scoring method was used to select participants, the individual risk factors of the two groups may have been different. For instance, we have found that two or more previous preterm deliveries carries a 2.5-fold greater risk (70%) than one previous preterm infant (30%). Alternatively, the diagnosis of actual preterm labor may have been incorrect. Table II indicates a greater number of women were treated with oral tocolytic agents in one group even though approximately equal numbers of women were treated with parenteral drugs. This may indicate that uterine irritability without cervical change was treated as preterm labor. Would the authors comment on the criteria for diagnosis and treatment of preterm labor in this study?

Not only were the capabilities of ultrasonography tested in this study, but there was an opportunity to determine the effect of bimanual examination on the occurrence of preterm labor and premature rupture of membranes. Although several studies have shown no adverse effects of weekly cervical examinations in preterm gestations, there is at least one study in term pregnancies indicating a greater incidence of premature rupture of the membranes in women who receive regular pelvic examinations than in those in whom the routine examination is omitted.[4] In this article no statistical difference was found between the two groups, suggesting no effect. This is reassuring to those of us who use pelvic examinations in patients at risk for pre-

term delivery. The incidence of premature rupture of the membranes in this study is not reported; this is a factor that might be important in women at risk for preterm delivery. To study the question of cervical manipulation and preterm delivery, it is also necessary to exclude patients who have had extensive manipulation with a cerclage procedure. These patients comprised a large proportion of the authors' study group. If patients undergoing cerclage are excluded, does weekly cervical examination influence the outcome?

Despite the negative findings of the study, a sufficient number of patients were included to reach the conclusion that weekly ultrasonographic examination of the cervix offers no benefit over current standard practice. The findings support our clinical experience. A cost analysis of such a program of ultrasonographic examination would also support the current approach of routine bimanual examination.

DR. KENNETH J. LEVENO, Dallas, Texas. Early identification of pregnancies at risk for preterm birth is currently receiving major emphasis since prevention is preferable to active treatment of preterm labor. Although women with prior preterm births are clearly at risk for recurrence, there is increasing interest, as evidenced by the authors' report, in other risk factors, such as asymptomatic cervical effacement and dilatation after midpregnancy.

Interestingly, "premature" cervical change as a risk factor for preterm birth is a relatively recent observation. Until this decade conventional obstetric teaching has held that asymptomatic preterm cervical dilatation is a normal anatomic variant, especially in parous women.

Between 1961 and 1969 five investigations on the significance of early third-trimester cervical dilatation were published. In three reports it was observed that such cervical change was not linked to preterm birth,[1-3] whereas an association was found in the other two studies.[4,5] During the next decade identification of pregnancies at risk by means of scoring systems based on socioeconomic status, reproductive history, daily habits, and current pregnancy complications received impetus as a result of pioneering work by Papiernik and Kaminski[6] and Creasy et al.[7] Preterm cervical dilatation was a risk factor in both scoring systems. At least three reports on precocious cervical dilatation were published during the 1980s and have confirmed this clinical finding as a harbinger of preterm birth.[8-10] Therefore I believe we must conclude that early third-trimester cervical dilatation is meaningful in predicting the risk of preterm labor. Unfortunately, detection of such cervical change has required manual examination, which may have unwanted consequences. Specifically, manual examination of the cervix at term has been reported to triple the frequency of membrane rupture before labor.[11] The recent development of high-resolution ultrasonographic technology that permits cervical imaging as now described by the authors inevitably is an attractive alternative to manual examination of the cervix.

Dr. Lorenz and colleagues designed their study to compare the effectiveness of cervical assessment by ultrasonography with manual pelvic examination in the prevention of preterm labor and found no advantage for ultrasonographic evaluation. This is the first reported randomized investigation with this goal. Actually, this investigation is based on the somewhat novel concept that ultrasonographic examination may itself be a therapeutic intervention rather than simply a diagnostic modality. Whether use of ultrasonography is "therapeutic" is an important and timely subject given the widespread application of obstetric utlrasonography, arguably without proof of benefit. Indeed, ultrasonography could be construed to be harmful on the basis of this investigation because preterm labor occured twice as often in the ultrasonography group. Alternatively, we can also conclude that manual examination of the cervix is not harmful.

I have two primary criticisms of this investigation. First, given the several vagaries involved in the diagnosis and management of preterm labor, I suspect that the sample size used may be too small to judge the efficacy of ultrasonography as a "therapeutic" intervention. For example, most investigations that concern the interventional merits of ultrasonography include hundreds and even thousands of pregnancies. Second, I am not convinced that sufficient experience with cervical ultrasonography has been published so that we can firmly conclude that it is as useful as manual examination in assessing either cervical condition or risk of preterm labor. The authors' study may have the perfect design necessary to address these roles of cervical ultrasonographic imaging compared with manual examination. Therefore I suggest an analysis of the data presented to answer the question, "How does cervical ultrasonography compare with manual examination in the *prediction, not prevention,* of preterm labor?" I think this information would be particularly useful since avoidance of cervical manipulation in pregnancies at risk for preterm labor could potentially be very important.

DR. STEPHEN L. BLOOM, Waterloo, Iowa. My question is not directly related to the purpose of the article. How do you treat women with cervical effacement, dilatation of the cervix, or both, in the last 4 months of pregnancy when there is no evidence of uterine contractility?

DR. RUDI ANSBACHER, Ann Arbor, Michigan. I have one question. Do you think if you had done this study with an indigent population whose members were socioeconomically deprived, you would have found different results?

DR. JOHN A. GARBACIAK, JR., Phoenix, Arizona. I would like Dr. Lorenz to comment on the bladder manipulation that was necessary for the weekly ultrasonographic examination—was this potentially an irritating factor causing uterine irritability or what he defined as preterm labor?

DR. EDUARD EICHNER, Cleveland, Ohio. I want to go back years again as a historian. I did work with relaxin to stop labor 40 or 50 years ago when some groups used relaxin to examine a softened cervix and to make it soft. Vaginal examination helped produce labor in some women by pushing the finger through the cervix so soft that it would admit it.

We started with our original group of women with ruptured membranes suspected as the cause of labor, and we were the first to report that ruptured membranes by themselves did *not* produce labor unless the pregnancy was close to term. The ratio was reversed the longer from true term gestation, with less likelihood of labor production.

The only question involved is the question of the vaginal examination. Do you just examine or do you do some manipulation?

We lost pregnancies in our patients with premature rupture of membranes very far from term because of amnionitis that developed because of ruptured membranes. We were able to show that ruptured membranes per se did not produce labor except at term.

We used relaxin, which softened the cervix. If there was no sexual activity involved and no other manipulation except the pelvic examination, the examination itself did not produce labor.

DR. L. RUSSELL MALINAK, Houston, Texas. Given the variability of the anatomy of the external cervical os as a result of distortion from previous lacerations, large nabothian cysts, or other factors, is that site an optimum end point for measuring the length of the cervical canal?

DR. LORENZ (Closing). I would like to thank all the discussants for very cogent comments. I will begin with Dr. Martin's comments. He questioned what the difficulties were with the ultrasonography technique. Certainly I would agree with everything that has been said about the problems with bladder volume. I refer to an excellent paper by Confino et al.[1] in 1986 that listed bladder volume as one of the pitfalls of ultrasonographic evaluation of the cervix.

The second problem we found very frequently after about 32 weeks' gestation. If the presenting part was relatively low in the pelvis, then evaluation of the cervix was virtually impossible.

The comments about criteria for diagnosis of preterm labor are extremely relevant and may explain our findings. The research team was working on surveillance of the patients who were asymptomatic. That included weekly visits with either method that we described, as well as patient education. If a finding of change on ultrasonography was noted, which we defined as a change of at least 1 cm shortening in length, then the attending physician was notified. The diagnosis of preterm labor and the management was the responsibility of the clinical team.

Most patients were private patients and remained under the care of their attending physicians. Just as there are considerable differences of opinion on the national basis regarding treatment for uterine irritability, uterine contractions, etc. this was the case in our institution. There were not many physicians involved, and the randomization was an attempt to try to control for this aspect. However, the basis of this study was the impact on the "bottom line" of the preterm delivery rate, and the preterm delivery rate did not appear to be different.

The question about risk scoring is also important. In the Creasy system 10 points, the maximum value, are allotted for a single preterm birth, and the number of preterm births was multiplied by 10. A patient with two previous preterm births would have double the risks, and so on. The rates of previous preterm births in the two groups were equal. Similarly, the risk scoring with the Creasy method was the same; thus I think the groups were similar from the standpoint of risk based on previous obstetric history.

The point about premature rupture of membranes was quite pertinent. We saw only two women with preterm premature rupture of membranes, and both patients had ultrasonographic evaluation. Similarly, the latent phase from the onset of ruptured membranes until delivery for the whole population was no different between the two groups. We analyzed these patients without the cerclage group, and our findings remained the same: there was no benefit to ultrasonographic evaluation.

Dr. Leveno's point about the therapeutic role of ultrasonography does relate to the fact that what we may be observing is that clinicians in 1986 to 1988 reacted more aggressively with therapy when an abnormality was detected by ultrasonography than clinicians who only had a report of a change of bimanual examination. We cannot prove that with these data.

Dr. Leveno suggests developing an ultrasonographic method for risk assessment. This would require a much larger sample size (Papiernik and Kaminski used 7000 patients for their pelvic examination risk assessment). Ultimately, the value of risk assessment lies in its ability to allow intervention to reduce preterm birth. In this article we described our ultrasonographic and bimanual pelvic examination criteria for identifying patients as being at increased risk, which allowed intervention, and then compared the ultimate result of the impact on preterm birth rates. We encourage further work on ultrasonographically based risk assessment, but have shown that there is no apparent benefit to ultrasonography versus bimanual examination for surveillance of the cervix.

I think the other comment about the possible effect of bladder filling on uterine activity may also be relevant. Certainly we see many patients at risk for preterm labor who report much more frequent contractions when they have a full bladder; in fact, when they void the uterine activity is then reduced. This is speculation at this point.

The vagaries related to diagnosis mentioned by Dr. Leveno are well accepted. I suggest that the value of this study does not rest on the diagnosis of preterm labor, however, that finding of preterm labor may be an indicator of potential problems. We hope to continue our work and study the ultrasonographic information we have collected to try prospective risk assessment as Bouyer and others have done with an actual relative risk based on cervical length. I think we should be able to do that, as Dr. Leveno suggested.

Dr. Bloom asked how we manage the patient with cervical effacement and dilatation without uterine contractions. In this study, the managment was determined by the attending physician. Our suggestions would be to review the patient's clinical circumstances and to monitor uterine activity. This may occur in the asymptomatic patient who should reduce activity and have increased surveillance, even if she were at low risk for preterm birth.

Dr. Ansbacher's comment about the indigent population is a good one. There has been extensive work in Philadelphia that suggests that treatment or interventions that are successful in one population for prevention of preterm birth may not work in another. We cannot address that at this point; it would be only speculation.

Sacrospinous ligament fixation at the time of transvaginal hysterectomy

Stephen H. Cruikshank, MD, and Donald W. Cox, MD

Minneapolis, Minnesota, and Morgantown, West Virginia

Sacrospinous ligament fixation of the vagina was performed on 48 of 135 patients at the time of transvaginal hysterectomy. All 48 patients in the group had at least moderate or severe uterovaginal prolapse and symptomatic pelvic relaxation, which is described herein. In five patients cystoceles developed, in two patients rectoceles developed, and one patient has had vault prolapse subsequent to surgery. Morbidity was minimal. Postoperative results indicate that sacrospinous ligament fixation of the vagina can be a useful adjunctive procedure when performed at the time of vaginal hysterectomy. (Am J Obstet Gynecol 1990;162:1611-9.)

Key words: Sacrospinous ligament fixation, uterovaginal prolapse

Vaginal vault prolapse is considered an infrequent yet tragic (by the patient) complication after hysterectomy. Estimates in recent literature of its incidence range from 0.2%[1] to 1.0%.[2] The literature is replete with methods of repairing vault prolapse. Largely because of the work of Randall and Nichols,[3, 4] the use of sacrospinous ligament fixation to correct this condition has had a resurgence in the United States. Consistent with the consensus in the literature, Morley and DeLancey[5] have characterized this procedure as being for therapeutic purposes only.

This article recommends that sacrospinous fixation be performed at the time of transvaginal hysterectomy as an adjunctive measure to be used with patients at risk for vaginal vault prolapse. We recount the results of such surgery on 48 patients and offer this article as a complement to a previously published report.[6] We hope the readers will read the discussions and our closing statement to get the full flavor of this presentation.

Material and methods

Sacrospinous fixation of the vagina was performed on 48 of 135 patients undergoing vaginal hysterectomy for benign disease. Besides the indications for operation listed in Table I, all 48 patients had moderate to severe uterovaginal prolapse with or without symptomatic pelvic relaxation. Moderate uterovaginal prolapse was defined as the presentation of the cervix past the midportion of the vagina or to the introitus as a result of Valsalva's maneuver (Fig. 1). Severe uterovaginal prolapse was defined as presentation of the cervix past the introitus with or without Valsalva's maneuver (Fig. 2). The uterosacral-cardinal ligament complex was totally lax (surgically weak) or nonexistent in all 48 patients at the time of operation. These structures were unavailable to shorten or attach for support, although an attempt was made. Only the material relevant to the use of the sacrospinous fixation at the time hysterectomy is discussed. Other important details of this operation have been presented by Nichols and Randall,[4] Miyazaki,[7] and, most recently, Morley and DeLancey.[5]

The ages of the patients ranged from 33 to 81 years with a mean of 50 years. These patient characteristics were noted: age, weight, surgical indications, parity, and secondary diagnoses. All patients were screened with Papanicolaou smears and colposcopy when indicated. Patients gave informed consent for all procedures. The surgeons included one faculty member (S. H. C.), a gynecology resident, and at all times the referring physician, who was present to learn the procedure.

One hundred thirty-five patients underwent transvaginal hysterectomy as described in two standard texts.[4, 8] Forty-eight of these patients fulfilled criteria as defined above to have a sacrospinous fixation performed as well. A previously reported method[6] of attaching the uterosacral-cardinal ligament complex to the vaginal membrane for prevention of posthysterectomy vault prolapse was attempted in all cases (Fig. 3). In all 48 cases the laxity or lack of the uterosacral-cardinal ligament complex made it difficult to shorten or attach these for support. Therefore, after the hysterectomy was completed, the sacrospinous ligament

Table I. Indications for operation

Primary indication	*No. of patients*	*No. of patients with concurrent uterovaginal prolapse (only)*	*No. of patients with concurrent symptomatic relaxed vaginal outlet and uterovaginal prolapse*
Stress urinary incontinence	4	1	3
Grade 2 or 3*	9	6	3
Refractory dysmenorrhea	14	10	4
Recurrent postmenopausal bleeding	5	5	0
Dysfunctional uterine bleeding	16	10	6
TOTAL	48		

*Includes patients desiring sterilization with biopsy-proved grade 2 or 3 cervical intraepithelial neoplasia.

was identified. The ligament fixation procedure was performed as follows: (1) The posterior vaginal wall was opened to the apex and the rectovaginal space entered. (2) This was dissected with the operator's finger to the level of the ischial spines. (3) At that time the descending rectal septum (pillar) was perforated, opening the pararectal space (Fig. 4). With additional blunt dissection, the ischial spine and the coccygeus muscle–sacrospinous ligament were palpated and identified. (4) No. 2 Vicryl sutures were placed through the ligament (Fig. 5). These were held and left untied until any additional reconstructive procedures were completed. (5) Last, the sacrospinous ligament fixation was carried out with the use of both safety and pulley stitches[4] (Fig. 6).

Results

Transvaginal hysterectomy was accomplished in all 135 patients. Forty-eight adjunctive sacrospinous fixations of the vagina were carried out in these same patients. There were no injuries to the rectum, nerves, or bladder. In two cases, significant bleeding occurred from the perirectal veins, necessitating transfusion. The bleeding was stopped and there were no adverse sequelae as a result of injury to these vessels.

The morbidity and complications were low. All patients received prophylactic cephalosporin antibiotic therapy. Forty-four (92%) of the 48 patients remained afebrile throughout the postoperative course. Of the four patients with febrile morbidity (oral temperature of ≥37.9° C), three had a urinary tract infection and

one had no demonstrable cause. The average blood loss was 290 ml for all procedures; average blood loss for sacrospinous ligament fixation was 100 ml. The average time for the entire operation was 2 hours 20 minutes (in a teaching setting), and the average time of the sacrospinous fixation procedure was 18.5 minutes. The average hospital stay was 6.2 days.

Four patients with concomitant anterior colporrhaphy were unable to urinate before discharge from the hospital. All were sent home with Foley catheters in place. All four patients have urinated since then. Two patients had transient stress incontinence from the sacrospinous procedure, but this complication resolved in both cases. Twenty patients complained of right buttock pain. All had spontaneous resolution by their 6-week postoperative checkup. All patients have been followed up from 8 months to 3.2 years without evidence of posthysterectomy vaginal prolapse, except in one patient. All patients were examined 6 weeks postoperatively. In both the supine and the standing position the patients were asked to elicit a Valsalva maneuver. The mean follow-up time has been 2 years.

Subsequent minor complications were without sequelae. In five patients anterior wall relaxation developed postoperatively without evidence of stress urinary incontinence. None of these had anterior colporrhaphy with our initial procedures. In two patients rectocele developed postoperatively. Neither had a posterior colporrhaphy with the initial operation; they elected not to have this complication repaired. Twenty-five patients had anterior colporrhaphy for urinary stress incontinence and/or symptomatic anterior vaginal wall relaxation. Eighteen patients had posterior colporrhaphy in addition to anterior repair. Five patients had an enterocele repaired, and seven additional patients had posterior colporrhaphy only. To date there has been one reported case of posthysterectomy vaginal vault prolapse.

Comment

Traditionally, sacrospinous fixation has been regarded as a therapeutic tool to be used only for repair

of vaginal vault prolapse.[3, 5] However, I feel that this procedure also may be used as a prophylaxis (as defined herein) against posthysterectomy vault prolapse. Not every vaginal hysterectomy patient is a candidate. If there is a loss of pelvic supportive structures (uterosacral-cardinal ligament complex) noted at the time of hysterectomy, an attempt to use their remnants should be made. However, sacrospinous fixation as an adjunct will prevent further vault prolapse. Nichols and Randall,[9] in their most recent textbook, state that without strong pelvic support a sacrospinous colpopexy is easy to perform after vaginal hysterectomy.

The 48 patients in this study represent only 35% of the vaginal hysterectomies performed during this time period. I stress again the point that the adjunctive sacrospinous fixation is not to be used universally in all vaginal hysterectomies. In these other 87 patients the uterosacral-cardinal ligament complex was attached only, and a sacrospinous ligament fixation was not required.

Previously a method was described that uses the pelvic supportive structures (the cardinal-uterosacral ligament complex) to help prevent subsequent prolapse.[6] These steps hold the vagina in its almost horizontal position above the levator ani; however, if these supportive structures are not present, the vaginal apex is still at risk for prolapse. In all 48 patients the apex was drawn past the introitus after the hysterectomy and any plastic repair. We feel it is appropriate during transvaginal hysterectomy to attempt support of the vagina in its normal anatomic position. Moreover, if moderate or severe uterovaginal prolapse exists as well, either as the main indication or as a secondary diagnosis, the pelvic surgeon should use the sacrospinous fixation to correct this, thus preventing future complications and sparing the patient from further procedures. Sacrospinous ligament fixation is not to be performed universally at the time of hysterectomy. Out of 135 patients undergoing vaginal hysterectomy, only 48 fulfilled the prerequisites for sacrospinous fixation of the vaginal vault. We feel this is an appropriate adjunctive-prophylactic procedure if strict criteria are met: (1) total laxity of the uterosacral-cardinal ligament complex, (2) moderate to severe laxity of the supportive structures and the ability to pull the vaginal apex to or past the introitus after hysterectomy and other plastic procedures, and (3) total procidentia at the time of hysterectomy.

Various principles of vaginal fixation during hysterectomy are recognized today. At all times the surgeon should note the laxity of the supporting structures and attempt to repair this at the initial operation.

Transvaginal hysterectomy offers a good opportunity to prevent future vaginal prolapse. Considering the results of this study, it seems feasible to add the sacrospinous fixation as a procedure in cases of vaginal hysterectomy presenting with moderate to severe uterovaginal descensus and loss of pelvic support. The procedure carries minimal morbidity, supports the vaginal apex, and provides the pelvic surgeon with an additional prophylactic measure against posthysterectomy vaginal prolapse.

Discussion

DR. GEORGE W. MORLEY, Ann Arbor, Michigan. At the outset, I wish to compliment the authors on their well-presented thesis and on their endeavor to put forth an additional surgical procedure to prevent vaginal vault prolapse after vaginal hysterectomy. In the interest of time, however, whereas I strongly believe sacrospinous ligament fixation as a *treatment* of vaginal vault prolapse is a significant step forward in our *therapeutic* armamentarium, I must respectfully challenge their recommendation of it at the time of vaginal hysterectomy as a *prophylactic* measure against vaginal prolapse in the future. With the possible exception of a total procidentia, I must question the indication for this operation as an adjunct to vaginal hysterectomy.

In the manuscript it is stated that all 48 patients on whom the prophylactic procedure was performed, had moderate to severe uterovaginal prolapse with or without symptomatic pelvic relaxation. I personally think the more traditional definitions of uterine prolapse could have been used rather than the terms *moderate* and *severe* since most textbooks of gynecology describe uterine prolapse by degrees. In the authors' terms, however, how many cases were classified as moderate and how many as severe? Also were there any third-degree procidentias in their series?

It is also stated that the uterosacral and cardinal ligament complex was totally lax or nonexistent in all 48 patients. One wonders what method was used to ascertain this impression since in my experience attach-

ment of the sacrouterine and cardinal ligaments to the vaginal apex (even though these ligaments may be markedly attenuated), high closure of the peritoneum, *and* the McCall-type culdoplasty have worked most satisfactorily as a preventive procedure.

In this study the authors performed a sacrospinous ligament fixation prophylactically on 48 of 135 patients undergong *vaginal* hysterectomy, giving a frequency of performance of 35.5%. And yet in their own introduction they quote from a review of the literature an actual incidence of vaginal prolapse after *both* abdominal and vaginal hysterectomy (with almost an equal distribution) a range of only 0.2% to 1%. Given then a 0.5% incidence of vaginal prolapse after vaginal hysterectomy alone, 200 patients would have to undergo this prophylactic procedure to prevent one prolapse instead of one patient undergoing it therapeutically at a later date.

In a further effort to compare the *infrequency* of vaginal vault prolapse with the *frequency* of hysterectomy, the most common major gynecologic procedure we do, I reference one report from the literature. A number of years ago, Symmonds and Pratt[1] from the Mayo Clinic reported that over a 15-year period, when >15,000 hysterectomies were performed in their institution, only 24 of these patients were treated for vaginal prolapse there during the same time period. They stated in their article, "Even if we allow for the possibility that an equal number of patients with vaginal prolapse may have obtained treatment of prolapse elsewhere, the incidence of prolapse following hysterectomy performed at this clinic has not been great."[1]

Finally, the risk/benefit ratio must be considered since this procedure is not without complication; i.e., excess bleeding requiring blood transfusions, sciatic or pudendal nerve inpingement, and postoperative sepsis. There have been at least two deaths probably related to this procedure.

In closing, the role of the discussant is first to anticipate the questions of the profession and second to represent the welfare of the patients who are possible candidates for any procedure that might be recommended. With apologies to the authors but in feeling a responsibility as the discussant, I must state that I consider the sacrospinous ligament fixation as a *prophylactic* procedure unwarranted in most situations!

I challenge the prophylactic procedure as adjunctive treatment after vaginal hysterectomy for these reasons: (1) because of the infrequency of vaginal prolapse when compared with the frequency of hysterectomy, (2) because of the operative risks and postoperative complications, which when encountered may be significant, (3) because of the additional cost (should there be a charge) of the procedure to the patient or payor, and (4) because of the potential failure of the *prophylactic* procedure in the future. Sixty-six percent or two thirds of our patients treated therapeutically at Michigan[2] experienced their initial symptoms of prolapse longer than 5 years after hysterectomy. The short-term follow-up of the patients treated prophylactically in the authors' series had a mean of only 21 months.

I have for Dr. Cruikshank one additional question out of curiosity. What was the incidence of prophylactic bilateral oophorectomy in your overall series?

I thank you for the invitation to discuss this manuscript, and again my apologies to the essayist.

DR. LESTER A. BALLARD, JR., Cleveland, Ohio. At the Central Association meeting in 1986, Dr. Cruikshank presented a paper entitled, "Preventing Posthysterectomy Vaginal Vault Prolapse and Enterocele During Vaginal Hysterectomy," in which he described 112 consecutive vaginal hysterectomies where there were identifiable uterosacral cardinal ligaments. He described his technique of shortening and attaching these ligaments to the vaginal vault for vault support, as well as a technique for enterocele prevention with the use of high peritoneal ligation incorporating the anterior wall of the rectum to close the posterior cul-de-sac. These 112 operations were done from July 1983 to March 1986, and the patients had a mean age of 30, ranging from 23 to 69 years. In my discussion of his paper, I asked what he did when the uterosacral cardinal ligaments were nonexistent or stringlike and not strong enough to support the vaginal vault, as in the older postmenopausal patient with severe prolapse. I mentioned that 38 (34.5%) of our 110 sacrospinous ligament fixations where there was third-degree uterine prolapse (mean patient age 63.5 years) were required as a primary adjunct to vaginal hysterectomy to maintain adequate vaginal depth and axis.

In their article the authors described a subsequent series of 135 vaginal hysterectomies where 48 patients required a sacrospinous fixation for vault suspension. This group of patients had a mean age of 50 (range 33 to 81 years) with the longest follow-up being 3.2 years. The authors have found sacrospinous ligament fixation to be a "useful adjunct" as a primary procedure done at the time of vaginal hysterectomy.

The indications for Dr. Cruikshank's vaginal hysterectomies in 1986 were dysfunctional uterine bleeding, grade 2 and grade 3 cervical epithelial neoplasia, refractory dysmenorrhea, stress urinary incontinence, recurrent postmenopausal bleeding, and symptomatic pelvic relaxation. In this report the indications were the same as in 1986, except there was no separate symptomatic pelvic relaxation group. The authors included 32 cases of vaginal prolapse and 16 cases of relaxed vaginal outlet with symptomatic uterovaginal prolapse

in these original five categories. I would have expected these patients to present with symptomatic pelvic pressure, bearing-down discomfort, protrusion, bleeding as a result of irritation, and urine irritability.

The authors illustrated and described patients with moderate degrees of prolapse, defined as the presentation of the cervix past the midline portion of the vagina or to the introitus, and severe prolapse, defined as presentation of the cervix past the introitus but showing the body of the uterus in the vagina.

It is interesting that Drs. Morley and DeLancey[2] refer to the criteria of Wilson and Carrington, which describe a first-degree prolapse as the cervix being between the level of ischial spine and vaginal introitus, second-degree prolapse as the cervix protruding through the introitus while the corpus remains in the vagina, and third-degree prolapse as complete prolapse of both the cervix and body of the uterus past the introitus and the entire vaginal canal everted. Therefore Dr. Cruikshank's moderate prolapse is Drs. Morley and DeLancey's first-degree, and Dr. Cruikshank's severe is Drs. Morley and DeLancey's second-degree and questionably third-degree together. Can the authors tell us how many cases were in the moderate and severe categories and did they include complete procidentia in the severe group?

The authors described uterosacral cardinal ligaments as totally lax or nonexistent in all 48 patients. Their structures were unavailable to shorten and attach for support although an attempt was made. They presented three criteria for adjunctive prophylactic use of the sacrospinous ligament fixation at vaginal hysterectomy: (1) total laxity of the uterosacral cardinal complex, (2) moderate to severe laxity of the supportive structures and the ability to pull the vaginal apex past the introitus after hysterectomy and other plastic procedures, and (3) total procidentia. Being able to pull the vaginal apex past the introitus after removal is a new criterion. I certainly concur with the third criterion of total procidentia. Does one have to have all three criteria or just one or two?

As a result of the authors' follow-up (mean 2 years), five anterior wall relaxations and two rectoceles were found; none of these patients had associated anterior and posterior colporrhaphy at the time of the sacrospinous ligament fixation. It is interesting that 37.5% of their patients had anterior-posterior repairs, 14.6% had anterior repairs only, 14.6% had posterior repairs only, and 33.3% had neither anterior nor posterior repair. Five patients had enterocele repairs, and one had vault recurrence.

In our current series of 268 sacrospinous ligament fixations, 233 (87%) of our patients had anterior-posterior repairs, 29 (10.7%) had posterior repairs only, 3 (1.1%) had anterior repairs only and 3 (1.1%) had no repair. Six had vault recurrences. Because of our original anterior wall recurrences and anterior enterocele with vault recurrence, I have increased the percentage of anterior-posterior wall repairs, even if only minor degrees of weakness are evident, to attempt to prevent these recurrences.

In Dr. Nichols' series of 163 patients, 59 (27.6%) cases were primary. In our own series of 268 sacrospinous fixations, 79 (29.5%) cases were primary. Dr. Nichols and I feel that primary sacrospinous fixation should be done at the time of vaginal hysterectomy when there are no surgically useful uterosacral cardinal ligaments for support of the vaginal vault. When cardinal uterosacral strength is lacking, an alternate method for vault suspension should be found. I would prefer not to rely on inadequate uterosacral cardinal ligaments for support or to have to depend on flimsy perirectal fascia and supralevator fascia support, for which one sacrifices depth and caliber. The latter procedure is good in the patient who does not want to maintain coital capacity.

I concur with Drs. Morley and DeLancey that prophylactic use of sacrospinous ligament fixation for "usual" or mild to moderate degrees of uterine prolapse is not usually needed and is an additional unnecessary financial burden. Hoerr's law, as used at the Cleveland Clinic, states, "It is difficult to make the asymptomatic patient feel better with surgery." In patients with good uterosacral cardinal ligaments that can be shortened for vault suspension, there is no need to perform a sacrospinous ligament fixation. However, in the patient with severe and complete uterine prolapse without surgically usable or identifiable ligaments, I would prefer to use sacrospinous ligament fixation. Drs. Morley and DeLancey also state that ". . . sacrospinous ligament fixation should be classified as a therapeutic procedure with the only reservation possibly being in patients with complete uterine prolapse as defined by Wilson and Carrington."

I will look forward to follow-up reports of Dr. Cruikshank's 1986 and present series regarding the prevention of vaginal vault prolapse.

Dr. Scott Snyder, Columbia, Missouri. I would like to know how many of the 138 patients had retropubic urethropexies and how this influenced the decision to do the sacrospinous ligament fixation.

Dr S. Robert Kovac, St. Louis, Missouri. I have a question to ask both Dr. Cruikshank and Dr. Morley. I'm a little bit confused, and maybe they can help me understand this better. Are we really quite sure what

the uterosacral-cardinal complex does anatomically to prevent vault prolapse? We need to decide whether this ligament complex supports the vagina or simply directs the vagina over the levator plate for support. Vault prolapse may be the result of a problem at a much higher pelvic level; therefore I think it is probably folly to rely on that particular complex as the sole definitive support of the vagina.

We must decide what anatomically we are attempting to accomplish with any type of plication procedures involving these ligaments. If we believe that these ligaments can prevent vault prolapse, then I think we must accept the consequences that we are going to have vault prolapse after some hysterectomies whether they are performed abdominally or vaginally.

However, sacrospinous fixation does not anatomically correct the cause of vault prolapse, but it does indirectly direct the vagina over the levator plate, perhaps better than plication procedures.

It appears to me that "the horse is out of the barn, and we forgot to close the gate"; now we're trying to catch up with the problem of preventing future vault prolapse. I think the most important issue is to actually determine and agree on what anatomic structures cause vault and uterine prolapse. Then we as gynecologic surgeons can design a specific surgical procedure to correct this problem and not rely on whatever we have used in the past to prevent this condition now and in the future.

Dr. Alan G. Waxman, Gallup, New Mexico. I wonder if, as Dr. Cruikshank expands his series, it might not be useful to introduce a comparison group, perhaps of the same patient population, randomized and operated on by the same surgeons so we can see if there really is efficacy from this procedure in the long run.

Dr. Bruce C. Richards, Lakewood, Colorado. In the appropriate case—and not to get into the controversy—for those that are interested in doing this procedure, I would endorse the notion of using the Mia hook. It is very facilitative.

Dr L. Russell Malinak, Houston, Texas. Was the cuff left open or was it closed in your patients with sacrospinous fixation? Does it matter?

Dr. Cruikshank (Closing). I am humbled. First of all, I would like to thank the discussants. I'm reading the book *Final Flight.* A quotation from it goes like this: "Confront the enemy with the tip of your sword against his face," and that's what I'm going to do in this debate.

The first thing I would like to say in respect to taking care of pelvic floor relaxation is that each aspect must be addressed to obtain optimal results. I think we need to keep that in mind when we're evaluating the patient in the office. I think the history and physical examination are probably the most important things, with the patient in the erect and the supine positions, not under anesthesia.

Once you make your surgical decision and find out in which quadrant or which anterior-posterior area you have a defect, then you can plan your repair; then a good pelvic examination with the patient under anesthesia should be done as well.

I anticipated this discussion so I brought one certain article to help me. This is Dr. Morley's article on sacrospinous fixation. He questions my indications and asked how many patients had procidentia. Procidentia was found in 8 patients. Severe prolapse as I defined it occurred in 24, moderate prolapse was found in 16.

To back my manuscript further, the abstract of Dr. Morley and Dr. DeLancey says that while 57 patients had a posthysterectomy complete vaginal prolapse, 38 patients had an incomplete vaginal prolapse. Again on page 873 it is stated: "The indication for operation was total vaginal prolapse in 57 patients (vaginal apex below the introitus), incomplete vaginal prolapse in 38 (vaginal apex at or above the introitus), and enterocele in five."

Now, if you recall my illustrations, the only differences between my criteria and his criteria is that the uterus is in situ in our patients. Once it's out, I then reexamine the patient and I've obtained his criteria. If I've done plastic repairs and I can still get the apex past the introitus or down to the introitus, then I've got the same problem as he does; that's why we have to take each defect and look at it individually and not just do a hysterectomy and say we solved it.

Uterine prolapse is not the cause of genital prolapse. It's a result. So if we have anterior wall relaxation, posterior wall relaxation, or enterocele, that's the result of genital prolapse; do we really know what causes it? Well, we're trying to find out, but we all have techniques that we're trying to use to cure it, and that's what I'm doing.

I would also like to read from Dr. Morley's article something else that parallels my manuscript (remember that the only difference is that the uterus is in situ in my patients until the hysterectomy is done): "Simply stated, all relaxations should not be treated as cystocele-rectocele." I have the feeling that that's what he wanted me to do as long as the uterus was in situ. This in my opinion would result in posthysterectomy degrees of prolapse.

Now, on page 878 of the article, I read: "An incomplete prolapse is present when any pathologic descensus down to the introitus exists. Any degree of descensus beyond this point is classified as a total vaginal prolapse. If further description of the prolapse is required, mensuration from the introitus as a reference point could be used."

I think I attempted to define that, and I tried to do that in the office when the patients came in; if they could perform a Valsalva maneuver of the uterus down to the introitus or past the introitus, there was more abnormality than just uterine prolapse. So I didn't want to do a hysterectomy and just say, "See you back after a while."

The complications in Dr. Morley's patient population were no different from the complications in mine or the complications of Dr. Nichols, and they're not as bad as the complications we see from episiotomies and ce-

sarean sections. We've got to do something about these routine—what we call therapeutic—operations that wreak a lot of havoc and have more morbidity than a sacrospinous fixation.

Now, 0.2% to 1% as the incidence of vault prolapse is in the recent literature. Gynecology is very interesting. What is old literature? In the 1960s reports say vault prolapse occurs in 1% to 43%; is that the old literature? And in obstetrics "current" means "5 years old." In gynecology though, what's old? So the 0.2% to 1% figure represents the literature of the late 1970s and 1980s. But in the older literature, in the 1960s, it was as high as 43%.

I spent some time in the Third World just this summer, and I can guarantee that some things are different. I was in Portugal. We had a whole ward of women who were seen with uterovaginal and vaginal prolapses, and there was close to if not more than 43% incidence. It may be their life-style or that the hysterectomy was performed wrong the first time. I don't know. It was very impressive.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Reproductive performance after methotrexate treatment of ectopic pregnancy

Thomas G. Stovall, MD,[a] Frank W. Ling, MD,[a] and John E. Buster, MD[b]
Memphis, Tennessee

The purpose of this study was to examine return of reproductive potential, hysterosalpingographic findings, and time to conception in patients treated with methotrexate and citrovorum factor for unruptured ectopic pregnancy. Fifty-seven patients with unruptured ectopic pregnancies <3.0 cm in greatest dimension were treated with methotrexate and citrovorum factor. The mean time from resolution of the ectopic pregnancy to return of menses was 26.0 (0 to 157) days. Forty-four patients were available for follow-up (2 to 15 months). Nineteen of 23 patients who had hysterosalpingograms demonstrated patency in the ipsilateral tube. Fourteen patients desired pregnancy; 11 of 14 (78.6%) were successful, with 10 of 11 (90.9%) having an intrauterine pregnancy, whereas one of 14 (9.1%) were extrauterine gestations. The mean time from first attempt to achieving pregnancy was 2.3 (1 to 4) months. We conclude that methotrexate and citrovorum factor treatment of unruptured ectopic pregnancy is associated with subsequent tubal patency and does not impair return of menses. Most importantly, the pregnancy rates after this form of therapy appear to be better than those achieved by traditional surgical methods, and are comparable to results after laparoscopic salpingostomy. (AM J OBSTET GYNECOL 1990;162:1620-4.)

Key words: Ectopic pregnancy, methotrexate, reproductive function

Previously only one third of women with a previous ectopic pregnancy had a subsequent live birth.[1, 2] More than 50% of these women were subsequently unable to conceive.[3] Although operative strategy has changed toward more conservative management, only 68% of patients treated conservatively with microsurgical techniques conceive and only 56% will have an intrauterine pregnancy.[4] Thus there is a need to seek treatment modalities with better reproductive potential.

Recent reports increasingly advocate the use of methotrexate and citrovorum factor for treatment of unruptured ectopic pregnancy.[5-7] Because it is safe, effective, and can be performed on an outpatient basis, medical treatment offers an attractive alternative to the patient and clinician. Tubal rupture and significant methotrexate–citrovorum factor drug-related side effects do occur, but these occur in less than 5% of patients, making this a very safe treatment.[7] The 5% incidence of rupture is comparable with the 3.5% to 10% incidence of persistent tubal ectopic gestation after conservative surgical procedures. In such patients a second surgical procedure or methotrexate chemotherapy is then required.[8, 9] Unanswered questions with regard to this form of therapy concern problems such as delayed restoration of menses, distorted tubal anatomy as a result of medical rather than surgical treatment, and poor reproductive performance.

To our knowledge no studies have addressed the question of subsequent reproductive performance in patients with ectopic pregnancy treated with methotrexate–citrovorum factor. In a large ongoing series, this article examines return of reproductive function in a group of women successfully treated with methotrexate–citrovorum factor for ectopic pregnancy and evaluates time to first menses, tubal patency, time to conception, and pregnancy location and outcome.

Material and methods

Beginning Nov. 1, 1987, an intensive screening program for the early diagnosis of ectopic pregnancy was begun at the University of Tennessee, Memphis. All patients without active liver disease diagnosed with unruptured ectopic pregnancies ≤3.0 cm in greatest diameter were eligible for outpatient treatment with methotrexate–citrovorum factor and were treated as previously described according to an Institutional Review Board–approved protocol.[7]

Until completion of treatment, defined as human chorionic gonadotropin (hCG) titer <10 mIU/ml, patients were asked to refrain from sexual intercourse. Patients were also counseled to use oral contraceptives, or double-barrier contraception for the 2 months after completion of therapy. Hysterosalpingograms were

6/6/19649

scheduled 7 to 12 days after the patient's first menstrual period. Patients were then counseled concerning pregnancy, and those desiring pregnancy were no longer required to use contraception.

Follow-up was performed every 2 to 3 months. Only those patients who completed therapy and underwent follow-up until March 1, 1989, are included.

Statistical analysis was performed with the life-table method. All values are reported as means ± 1 SD.

Results

During the study period 204 patients with ectopic pregnancy were diagnosed; 131 gestations (64.2%) were unruptured and 73 (35.8%) were ruptured. Of the 131 unruptured ectopics, 57 (43.5%) tubal pregnancies (study group) and one (0.76%) cervical ectopic pregnancy were treated with methotrexate–citrovorum factor.[10] Nine (6.9%) patients had ectopic gestations that regressed, whereas the remaining 64 (48.9%) were treated surgically. Of the 64 patients with unruptured ectopics treated surgically, 60 were not eligible for methotrexate–citrovorum factor treatment because of ectopic size or cardiac activity. The remaining four (6.3%) patients declined medical therapy.

Mean patient age was 26.9 ± 5.4 years (range, 16 to 38 years); gravidity ranged from 1 to 6 and parity ranged from 0 to 5. Twelve of the 57 (21.1%) patients in the study group had a previous ectopic pregnancy with six (50.0%) occurring on the right and six (50.0%) on the left. No patient had more than one previous ectopic gestation. Ten of 12 patients (83.3%) had previous salpingectomies for ruptured ectopics, whereas two had been treated previously with salpingostomies.

One to four doses of methotrexate–citrovorum factor were administered (mean, 2.5 ± 1.1 doses). The time from treatment to resolution (hCG titer <10 mIU/ml) ranged from 9 to 100 days (mean, 27.2 ± 16.5 days).

Forty-four of 57 (77.2%) patients with unruptured tubal ectopic pregnancies were available for follow-up; 13 (22.8%) were lost to follow-up. The time of follow-up ranged from 2 to 15 months.

Mean time to first menses, calculated from the last day of treatment, was 21.7 ± 26.0 days (0 to 157 days). Only one patient had delay of menses beyond 45 days, and 42 of 44 patients described regular menstrual periods with intervals ranging from 28 to 35 days.

Twenty-three patients had hysterosalpingograms after methotrexate–citrovorum factor treatment. Of 43 tubes present, 35 of 43 (81.4%) were patent with a normal appearance, and 8 of 43 (18.6%) were occluded. Two of the eight occluded tubes (25%) had cornual obstruction; the remaining six (75%) were obstructed more distally with hydrosalpinx and distorted tubal anatomy. In 20 of 23 (87.0%) patients, at least one tube was patent, whereas 19 of 23 (82.6%) patients had tubal patency on the side involved with the ectopic implantation (Table I).

Of the 44 patients available for follow-up, 30 (68.2%) were either using birth control or were not sexually active. The other patients had actively attempted to become pregnant after treatment. Of these 14, 11 (78.6%) achieved pregnancy. Although one patient (9.11%) of the 11 had a repeat ectopic pregnancy in the contralateral tube treated with methotrexate–citrovorum factor, 10 of 11 (90.9%) achieved an intrauterine pregnancy. One of these intrauterine pregnancies ended with a spontaneous abortion, and the other nine have reached the second trimester or have been delivered. One of the 11 had only one tube, whereas the other 10 patients had both tubes present. Eight of the 11 (72.7%) had hysterosalpingograms before becoming pregnant, all of which revealed bilateral tubal patency. The mean time from treatment completion to diagnosis of pregnancy was 5.0 ± 2.6 (1 to 10) months. The mean time to pregnancy calculated from the first attempt at conception was 2.3 ± 1.0 (1 to 4) months.

Life-table analysis demonstrates the probability of pregnancy after completion of methotrexate–citrovorum factor treatment of unruptured ectopic pregnancy to be 25% at the end of 1 month and 87% after 4 months of attempted pregnancy (Fig. 1).

Comment

This study describes, for the first time, return of reproductive function after medical treatment (with methotrexate–citrovorum factor) of unruptured ectopic pregnancy, expressed as resumption of menses, tubal patency, time to conception, and pregnancy outcome.

Our overall tubal patency rate was 81.4%. This is comparable to that reported by Sauer et al.[6] in a similar series of unruptured ectopic pregnancies treated medically. In a surgical series, Mitchell et al.[11] described hysterosalpingograms obtained in 13 women whose ectopic pregnancies were removed by linear salpingostomy. Only four of 13 patients had bilateral tubal patency, whereas six of 13 had unilateral patency (four contralateral tubes, two ipsilateral tubes), and three of 13 had bilateral occlusion. Although our patient population is similar to that described by Mitchell,[11] the patients in our series were diagnosed at an earlier gestation as a result of our intensive screening methods.[12] Because of the earlier diagnosis and successful medical therapy, less tubal damage could be expected. In a comparable series, Vermesh et al.[13] demonstrated patency of the involved tube in 16 of 20 (80.0%) and 17 of 19 (89.0%) patients undergoing salpingostomy by laparoscopic and laparotomy approach, respectively.

Presumptive ovulatory function returned promptly

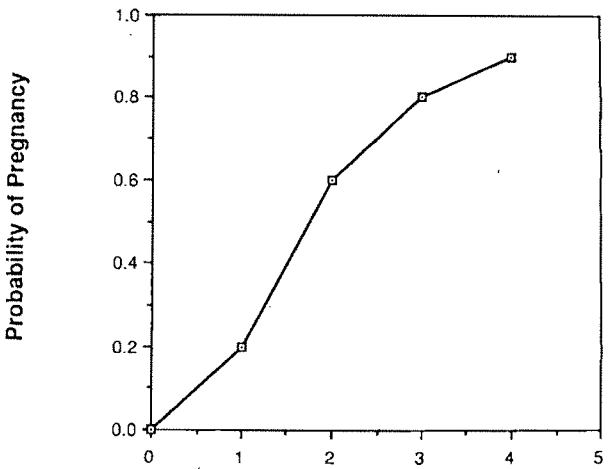

Fig. 1. Probability of pregnancy by time attempting conception after treatment with methotrexate.

Table I. Comparison of ectopic site with hysterosalpingographic findings

	Hysterosalpingogram findings			
	Patent		*Nonpatent*	
Ectopic site	*No.*	*%*	*No.*	*%*
Right (n = 18)	14	77.8	4	22.2
Left (n = 5)	5	100	0	00.0
TOTAL (N = 23)	19	82.6	4	17.4

after disappearance of hCG. In the majority of patients, normal menses returned just before completion of therapy or within the first 30 days after disappearance of hCG. In only one patient was this period longer than 45 days. Menses did not resume in this patient for 157 days at which time the patient sought treatment. The patient was morbidly obese and had withdrawal bleeding after a 10-day course of medroxyprogesterone acetate therapy. Kamrava et al.[14] showed that serum clearance of hCG may take up to at least 24 days after a conservative surgical procedure. Our mean time to disappearance of hCG is similar, although somewhat prolonged in a few patients with higher hCG titers. Thus use of methotrexate does not appear to unduly delay hCG disappearance or return of menses.

The probability of conception after methotrexate–citrovorum factor treatment is 25% and 87% at 1 and 4 months, respectively (Fig. 1). This is comparable to normal women with azospermic husbands who undergo artificial insemination with fresh semen. In one such series, Corson[15] found that 72% of pregnancies occurred by the end of the third cycle, a figure comparable to our study group (Fig. 1). However, our figures are somewhat superior to the surgical series of Vermesh et al.,[13] in which the pregnancy rate was 56% (10/18) in patients undergoing laparoscopic salpingostomy and 58% (11/19) in those treated by laparotomy salpingostomy. All pregnancies reported in this series were conceived within 6 months of operation. Our study is reassuring because 78.6% of patients (11/14) seeking pregnancy were able to conceive. However, our ability to draw firm conclusions is hindered by 22.8% of patients lost to follow-up after therapy completion and the small number of patients seeking pregnancy. It is also possible that the 44 patients available for follow-up and 14 patients attempting pregnancy are not representative of the entire study population.

On the basis of follow-up data available on patients treated with methotrexate for gestational trophoblastic disease, there does not appear to be an increased incidence of congenital malformation in subsequent pregnancies.[16] Although our study is not large enough to eliminate this possibility in this group of patients, it would seem unlikely given the current knowledge based on experience with gestational trophoblastic disease.

The intrauterine pregnancy rate of 90.1% in this series is superior to the 49% to 70% intrauterine pregnancy rate in patients treated by linear salpingostomy reported in a recent review.[16] In addition, our recurrent ectopic rate of 9.1% is comparable to the rate of 13% (0 to 22) reported in the same series. We speculate that the higher intrauterine pregnancy rate is not a result of methotrexate–citrovorum factor treatment alone, but a result of earlier diagnosis with an intensive screening program. By minimizing the time in which trophoblastic tissue can invade tubal mucosa, the risk of anatomic distortion with subsequent recurrent ectopic pregnancy is also lessened. We also hypothesize that medical therapy results in less tissue damage to the tube than any surgical procedure, regardless of how conservative the operation.

We conclude that methotrexate–citrovorum factor treatment of unruptured ectopic pregnancy does not impair return of menses, helps restore tubal anatomy as demonstrated by the hysterosalpingography, and does not appear to impair subsequent reproductive performance. The pregnancy rates after this form of therapy appear to be better than those achieved by traditional conservative surgical methods, comparable to laparoscopic salpingostomy, and comparable to normal women with azoospermic husbands who undergo artificial insemination with fresh semen. The principal value of this safe, effective form of treatment is that it bypasses the risk, cost, and morbidity of surgical intervention. This preliminary study is reassuring evidence that the benefits of methotrexate–citrovorum factor treatment are not offset by any loss of reproductive efficacy.

Discussion

DR. BRYAN D. COWAN, Jackson, Mississippi. To my knowledge, the first report of successful treatment of an ectopic pregnancy with methotrexate occurred in 1982.[1] After this report, a few case reports depicted anecdotal experience of unusual presentations of ectopic pregnancies including cervical pregnancy,[2] cornual pregnancy,[3] and persistent trophoblast[4] after conservative surgical management of unruptured tubal pregnancies. In 1985 the first clinical study of methotrexate as primary treatment for ectopic pregnancy was reported at the fifty-third annual meeting of this association in New Orleans.[5] Dr. Steve Ory and his colleagues described six patients with confirmed unruptured tubal pregnancies that were treated primarily with methotrexate. Since then several institutions have reported their experience in treating tubal pregnancies with methotrexate.

This report addresses an important question that all of us who have treated or have considered treating patients with tubal gestations with methotrexate have asked: "Do patients who undergo this treatment have preservation of tubal and reproductive function?" I am impressed with the authors' results.

Some aspects of this study, however, make the ultimate interpretation of this data difficult. For example, we do not know the status of the unaffected tube in the 14 patients who were attempting pregnancy. It is entirely possible that the unaffected tube was perfectly normal and therefore posed no risk for repeat ectopic pregnancy on the contralateral side or impairment of fertility. If the 10 patients who conceived an intrauterine gestation were disproportionately composed of women with normal contralateral anatomy, a distinct reproductive advantage would be granted to this group. On the other hand, women with contralateral tubal disease would be at risk for repeat ectopic pregnancy, and reduced fertility. An additional shortcoming is the failure to specify an ampullary or isthmic location for the ectopic pregnancy. The data cannot be analzyed to determine if patients with ampullary or isthmic tubal pregnancies have the same clinical outcome and subsequent reproductive potential after treatment with methotrexate. The trophoblast may invade the muscularis more aggressively in isthmic ectopic pregnancies,[6] and the subsequent outcome of these patients may be different than ampullary gestations.

I agree with the authors that this form of therapy, on the basis of their data, does not appear to impair subsequent reproductive performance. However, before we embrace this information completely, subsequent studies by other authors and other institutions should confirm these observations.

The claim that this therapy reduces the risk, cost, and morbidity of surgical intervention for ectopic pregnancy cannot be supported. All patients in this study underwent laparoscopy to confirm the diagnosis. It is exceptionally difficult for most gynecologists to recognize an ectopic pregnancy at the time of laparoscopy and allow this pathologic condition to be untreated by operation. Most gynecologists would remove the ectopic pregnancy and forego the cost of medical treatment. However, I can foresee when it may become practical to treat ectopic pregnancies without operation. Visualization by either ultrasonography or laparoscopy is currently required to confirm the diagnosis of an ectopic gestation. When an ectopic gestation can be defined without the need for operation, methotrexate therapy may be the treatment of choice. Ultrasonographically guided direct injection of methotrexate into

the gestational sac has successfully cured women in whom the ectopic gestation could be visualized.[7] Once diagnostic operation can be avoided, the true potential for this therapy as the primary treatment for tubal pregnancies will be realized. We are greatly encouraged by the favorable reproductive outcome reported here.

I have two questions for the authors. First, have they considered intraoperative injection of any ectopic gestations with methotrexate? Second, are they aware of the condition of the contralateral tube in the 10 of 14 women with an intrauterine gestation, and three who have failed to conceive, and one with a repeat ectopic pregnancy?

DR. M. WAYNE HEINE, Tucson, Arizona. The authors have provided additional information on return of reproductive function in patients treated medically for ectopic pregnancy. They studied return of menses, pregnancy rate, and pregnancy outcome. Menses returned within 26 days, and 82% of the affected tubes were patent after therapy. The pregnancy rate was 87% within 4 months, similar to donor insemination programs. The intrauterine pregnancy rate was 90%. This was compared with surgical treatment with a pregnancy rate of 57%, and the intrauterine pregnancy rate varies between 40% and 70%. The recurrent ectopic rate is similar in the two groups. Because of the restrictive criteria for a patient to enter the study, (i.e., tubal pregnancy of less than 3 cm in diameter), only 44 patients were available for follow-up of 2 to 15 months. Only 14 patients desired pregnancy. Because of this small number of patients (one patient in either direction), tubal pregnancy or abortion would alter the percentages greatly. The results are not comparable to the surgical method of treatment because the study patients had very early tubal pregnancies (less than 3 cm). The surgical series reported included more advanced tubal pregnancies. With more advanced tubal pregnancies there is more bleeding, distortion of the tubes, and invasion by the trophoblast. The method described by the authors is less costly and would save approximately $1200 per patient in our institution. There also should be less dissemination of trophoblastic materials with medical therapy.

The study would have been more informative if there had been an increased number of patients, and had alternated between medical and surgical therapy using the restrictive criteria. The comparison of reproductive function, morbidity, and cost would have been more meaningful.

DR. JOHN L. AUSTIN, Memphis, Tennessee. Dr. Stovall, what would be the appropriateness of a direct injection of methotrexate, perhaps during vaginal probe ultrasonography, in terms of both cost effectiveness and technical ability? Are you going to study this in the future?

DR. DANIEL A. RIGHTMIRE, Springfield, Illinois. Are the results so impressive that they preclude a prospective randomized trial?

DR. STOVALL (Closing). To update you on our progress, we have treated >80 unruptured ectopic pregnancies with methotrexate. Of these, 95% were successfully treated without further intervention. Of the three failures, two can be related to the presence of cardiac activity in advanced gestations with high hCG levels; the third rupture remains unexplained.

Current contraindications to methotrexate therapy include a size of ≥3 cm, rupture of the ectopic pregnancy, or the presence of cardiac activity. A study was recently reported in abstract form from Argentina in which the investigators treated ruptured ectopic pregnancies with methotrexate.

In the future, these contraindications outlined may become relative contraindications. Our group has treated approximately four patients with cardiac activity with low hCG levels, all of which have had successful outcomes.

To date, 16 pregnancies have occurred after methotrexate treatment; two of these were ectopics; and of some note, both were in the contralateral tube. Fourteen were intrauterine pregnancies. Thirteen of the fourteen intrauterine pregnancies are viable, and one ended with a spontaneous abortion.

The role of oral methotrexate in the treatment of this condition, the role of direct injection at the time of laparoscopy or at the time of vaginal ultrasonography (operative ultrasonography) remains uncertain. There are reports of oral methotrexate use, and there are reports with direct injection of methotrexate, potassium chloride, and prostaglandin. We have attempted direct injection with transvaginal ultrasonographic guidance on two patients. Both treatments failed.

Treatment of twins with hydramnios

To the Editors:

The report by Lange et al. on the treatment of twins with hydramnios (Lange IR, Harman CR, Ash KM, Manning FA, Menticoglou S. Twin with hydramnios: Treating premature labor at its source. AM J OBSTET GYNECOL 1989;160:552-7) prompts several important questions that are not clearly answered in the title, text, or diagrams. What is the zygosity of each twin pair? Were the placentas monochorionic or dichorionic? What were the hematocrit values at birth? What was the prenatal diagnosis for each of these pregnancies? Last, did each twin have hydramnios or did only one fetus have polyhydramnios whereas the other had oligohydramnios, as reported by Chescheir and Seeds?[1]

If the treatment group included pregnancies complicated by both polyhydramnios and oligohydramnios, then Lange et al. have presented a remarkable improvement in outcome without resorting to infanticide or serial amniocentesis. It is hoped that the authors have reported a medical solution to the vexing problem of twin pregnancies with concurrent polyhydramnios and oligohydramnios.

Hydramnios in twin pregnancy

To the Editors:

Lange et al. reported the results of treating six twin pregnancies that were complicated by hydramnios and premature labor (Lange IR, Harman CR, Ash KM, Manning FA, Menticoglou S. Twin with hydramnios: Treating premature labor at its source. AM J OBSTET GYNECOL 1989;160:552-7). Indomethacin was used both as a tocolytic agent and to reduce fetal urine output. The results are compared neither with previous cases, nor with controls in which this therapy was withheld, nor with cases in which other therapies were used.

We agree that hydramnios is a major cause of premature labor in twin pregnancy because it increases intrauterine volume above that caused by the twin pregnancy itself. Hydramnios may be caused by fetal anomalies, such as upper gastrointestinal tract obstruction or hydrops fetalis. Both of these anomalies may occur with increased frequency in twins. However, the most common cause of hydramnios in twin pregnancy is twin-to-twin transfusion, in which there are interfetal arteriovenous anastomoses in the parenchyma of monochorionic diamniotic placentas of monozygotic twins.[1] Hydramnios of the sac of the recipient may be accompanied by oligohydramnios of the sac of the donor, with the appearance of "stuck twin" in the donor. Twin-to-twin transfusion often results in premature labor in the early second trimester. Some cases are first seen clinically as acute severe polyhydramnios, which results in high perinatal mortality. Hydramnios in the sac of the recipient has been documented as being caused by fetal polyuria.[2] There usually is quite marked growth discordance.

In attempts prenatally to elucidate the causes of hydramnios in twin pregnancies, zygosity determination and placental anatomic studies are necessary. Several publications have documented the ability to distinguish monochorionic from dichorionic placentation in twins.[3] With the use of deoxyribonucleic acid restriction fragment length polymorphisms, zygosity can be diagnosed prenatally.[4] Postnatal documentation of placentation and zygosity is also mandatory.

It seems possible that pairs 1 and 6 of Lange et al. may have had twin transfusion syndrome to account for the hydramnios and growth discrepancy. It is not clear whether twins 5a and 6b both had congenital heart disease or whether there is a textual error.

We think that Lange et al. should clarify the issue of zygosity and placentation in their preliminary series and in any further publications. It is clear to us that hydramnios induced by twin transfusion has a distinctive pathophysiology, with recipient fetal polyuria. Twin pregnancies that are not monochorionic may have hydramnios of other causes. Alternative maneuvres, including repeat amniocentesis and selective birth, may be attempted in monochorionic twin hydramnios, but would not otherwise be appropriate.

We appeal to authors (and journal editors) to ensure that full information on zygosity and placental anatomy

is included in published data on complications and therapy in twin pregnancies.

Reply

To the Editors:

We appreciate the comments on our article and we are happy to address issues that these authors have raised.

First, with regard to the zygosity of each twin pair, monozygotic dichorionic placentas were confirmed in two twin sets (twins 1 and 4) and dichorionic, diamniotic placentas were confirmed in the remaining twins. In two twins (1 and 5) no membrane was seen at initial assessment, which did raise the possibility of monoamniotic monozygosity twins. With treatment a membrane subsequently became visible.

In case 1, the working diagnosis was a twin-to-twin transfusion. In case 5 congenital heart disease in one twin was suspected. In the remaining twins, inasmuch as growth profiles and Doppler ultrasonographic studies were normal, the cause for the gross hydramnios was unexplained.

The hematocrit values varied between cases, from 41.3% to 63.1%, but between twins the mean difference was small, averaging 3.8%. In only one pair did the difference in hematocrit exceed 5% (A = 41.3%, B = 52.7%). There was no significant discordance in cord pH, blood gas values, or Apgar scores. There was hydramnios in both twins in all cases before treatment. In three cases one twin showed a more marked diminution in fluid with indomethacin treatment than that of the other twin.

Subsequent to this report five further cases have been treated in a similar matter. In one case, there was unequivocal oligohydramnios in one sac and hydramnios in the other. Treatment was maintained from 27 to 31 weeks' gestation and labor occurred within 24 hours of discontinuing indomethacin. Transient oliguria was noted in the twin with oligohydramnios. There was clinical evidence of a twin-to-twin transfusion.

Study of preterm birth draws different interpretation

To the Editors:

Because we have participated in a multicenter trial of preterm birth prevention similar to that reported by Mueller-Heubach et al. (Mueller-Heubach E, Reddick D, Barnett B, Bente R. Preterm birth prevention: Evaluation of a prospective controlled randomized trial. AM J OBSTET GYNECOL 1989;160:1172-8) but achieved little success, we naturally were interested in the results of this study and wanted to make several observations. First, we learned as we were performing our trial that gestational age is a more ephemeral measurement than we initially believed.[1] We found that whereas the apparent gestational age distribution changed over time predominantly because of changes in the use of ultrasonography, the birth weight distribution and mean birth weight did not change. Because one possible explanation for the reported improvement in the preterm delivery rate over time is a change in the definition of gestational age, we would be interested to know, first, how the gestational age was determined, and second, what happened to the birth weight distribution over the time of their study?

It is, of course, encouraging to see a decrease in neonatal mortality over time. However, whereas the results are statistically significant there may be potential for bias in the results. For example, even though the authors admitted patients to the project at 20 weeks' gestation, which is equivalent to about 350 gm fetal weight, they nonetheless defined a neonatal death as those beginning at 500 gm, equivalent to about 23 or 24 weeks gestational age. Therefore the lower tail of potential mortality was excluded.

In addition, the authors do not present the neonatal mortality for the entire population studied, but only for those babies that by their definition were preterm. It would be interesting to know the neonatal mortality for the entire population admitted to the study and to see how this changed over time. In any case, neonatal mortality has improved over time in many institutions even when the preterm delivery rate did not. As an example, in the Mueller-Heubach article the neonatal mortality showed as large an improvement in the first year of the study, before any improvement in the preterm delivery rate, as occurred in subsequent years when the reported preterm delivery rate was lower.

However, even if the preterm delivery rate did change over time and the neonatal mortality improved, it is interesting to speculate what in the program may have led to these results. The authors state that the reason they believe the preterm delivery rate improved over time was that the method to be tested (i.e., risk screening, weekly evaluation, teaching) was adopted widely throughout their system. It is not clear from the methods section, but when the authors state that their entire prenatal system adopted the preterm prevention method, does this mean that the entire system went to a weekly visit with pelvic examinations and that this approach was applied to both high-risk controls and to their low-risk patients? This should be quantifiable and we would be interested in seeing these numbers. However, if that did not happen, the authors' statement about similarity in care between the high-risk treatment and all other groups should not be casually accepted because the difference in care between groups is important. For example, if the high-risk control and low-risk groups did not have weekly visits with examinations, it seems unlikely that the weekly visits and the weekly pelvic examinations played a significant role in the reduction in preterm delivery.

In regard to screening, inasmuch as nearly two thirds of the preterm deliveries came from the low-risk group, our calculations suggest that a substantial part of the improvement in the preterm delivery rate must have come from the low-risk population. If substantial improvement did occur in the low-risk group, then it seems safe to assume that screening for high-risk status was probably not of much value in producing the improvement. Also, because there was no significant difference in outcome between the high-risk treatment and control groups, it also appears that it is of little value to actually classify patients and move them into a high-risk group.

Because it seems that neither the screening, nor the classification, nor the weekly visits, nor the weekly pelvic examinations are plausible explanations or even necessary components for the improvement over time, it is not apparent to us which components of the program may have been responsible for its success. Certainly none of these program components is likely to be responsible for the reduction in the *diagnosis* of preterm labor, especially because the entire program was designed not to reduce the incidence of preterm labor, but to diagnose it early and treat it appropriately.[2]

Finally, we would like to remind the readers that the primary hypothesis and the study design involved a randomized trial of a specific intervention. This study design failed to show any benefit. In fact, although not statistically significant, the treatment group had a worse outcome (with a preterm delivery rate of 22.1% in the intervention group and 20.8% in the control group). This was also true in Philadelphia in a study by Main et al.[3] and in our part of the multicenter trial in Alabama.[4] It seems to us that what is important in this study is the result of the randomized trial, and its failure should not be so casually explained. Again, the Mueller-Heubach article and the Main[3] article, the only two randomized trials of this method of prematurity prevention that are now in print, failed to show any difference between the treatment and the control group. Certainly the authors did not prove that "the preterm birth rate . . . could be markedly decreased as a result of medical provider and patient education" nor did they show "that an intensive educational program among patients and providers can have a marked impact on the frequency of preterm birth." It is important to reread the title of this paper—"Preterm birth prevention: Evaluation of a prospective controlled, randomized trial." The results were negative. Any other interpretation, we believe, is misleading.

Conclusions lack support

To the Editors:

After reading E. Mueller-Heubach et al.'s article, (Mueller-Heubach E, Reddick D, Barnett B, Bente R. Preterm birth prevention: evaluation of a prospective controlled randomized trial. AM J OBSTET GYNECOL 1989;160:1172-8), my evaluation of their study was very different from theirs. The authors concluded that "we were able to demonstrate that an intensive educational program . . . can have a marked impact on the frequency of preterm birth." I found no support in their article for this conclusion.

The authors assumed that the general change in attitude of medical personnel explains the lack of difference in preterm births between the intervention and the control groups. Were the controls seen weekly from 22 to 37 weeks' gestation as was the intervention group, and did they have weekly cervical examinations? Did the controls have the same intensive teaching with regard to symptoms and signs of preterm labor as did the intervention group? Were the amounts of rest, cessation of smoking, and use of tocolysis the same in both groups? From the description in the methods section, the answer has to be no! Yet, as noted, the authors did not find a difference in preterm births between the control and intervention groups. Does this mean that

none of these intervention techniques is important? A possible answer to the findings of this most unique "prospective controlled randomized trial" is that during the time of the study the socioeconomic status of their entire clinic population changed to be more like that of the private population.

In attempting to reduce the prematurity rate in Denver in pregnant clinic populations, our success has been limited by the noncompliant patient, by the users of street drugs, and by those patients who have no message telephone. In addition, the authors did not mention how gestational age was estimated. We now seem to have more mature small-for-gestational-age newborns (as judged by nursery personnel) than in the past, which improves our rate of premature births. In contrast to this bleak record, Hispanic patients appear to be reducing their rates of premature births. Is it possible that these detrimental factors do not operate in Pittsburgh? What was the outcome in the authors' "refuser" group? Perhaps this group can solve the puzzle of why the controls did so well.

Reply

To the Editors:

We appreciate the comments of Goodlin as well as Goldenberg et al. with regard to our article. In response we would like to reemphasize the comment in our article that "we noted that the change in attitude of the medical personnel toward this preterm birth prevention program defeated the controlled randomized design of the study because management of the control group was not the same as it would have been before the onset of the study." For this reason, we titled our article "evaluation" rather than "results" of a prospective controlled randomized trial. As a result of our educational sessions, medical providers on their own began to give more instruction about preterm labor to patients irrespective of their risk assignment. We thought that it would be unethical and probably futile to ask medical providers not to do this, whereas we fully realized that our results would not be those of a prospective controlled randomized trial. Cervical examinations in patients not in the high-risk intervention group may have been more frequent but certainly were not done weekly, and we must conclude that weekly cervical examination did not contribute to the decrease in preterm birth rate. As we have pointed out, the decrease in preterm birth rate over time was a result of fewer patients first seen in preterm labor rather than more patients in preterm labor first seen as candidates for tocolysis.

With respect to determination of gestational age we used last menstrual period, size of uterus at early examination, quickening, and other clinical information. In cases of uncertainty and discrepancy early ultrasonographic examination was done and gestational age was adjusted when there was a ≥2-week discrepancy. Gestational age estimates were verified after delivery by Dubowitz scoring by the pediatrician. In contrast to Goldenberg et al. we have not changed our ultrasonic measurement techniques of the fetus during our study and thus have been spared the difficulty that they had in their preterm birth prevention study. We agree with Goldenberg et al. that on the basis of our results, screening for high-risk status is of limited value. In turn we suggest education of all pregnant patients about subtle symptoms and signs of preterm labor, uterine palpation and rest, and self-hydration when more than occasional uterine activity is noted.

We are aware that others have not observed a decrease in preterm birth rate in preterm birth prevention studies. This may be because of differences in patient population as suggested by Goodlin. Recent analysis of our study population by race revealed a very significant decrease in preterm births ($p < 0.001$) in 2446 white indigent patients in year 2 and 3 of the study with preterm birth rates lower than those in our white private population. In contrast, in 2599 black indigent study patients the preterm birth rate decreased much more modestly, reaching statistical significance ($p < 0.01$) only in year 3 of the study despite particular efforts to communicate with our black study population. It appears from our results that preterm birth prevention studies that involve predominantly black indigent patient populations and small sample sizes are not likely to show significant changes in preterm birth rate.

Volume and timing are key to use of intraumbilical oxytocin for management of retained placenta

To the Editors:

I read with great interest the article by Reddy and Carey (Reddy VV, Carey JC. Effect of umbilical vein oxytocin on puerperal blood loss and length of the third stage of labor. Am J Obstet Gynecol 1989;160: 206-8).

As they state in the Comment section, some controversy concerning the value of intraumbilical injection of oxytocin for the management of the third stage of labor or for the retained placenta does indeed exist.

As for the routine use of oxytocin in the management of the third stage of labor, the above study clearly shows in a randomized controlled manner that this maneuver shortens the length of the third stage of labor and diminishes blood loss. This confirms a previous observation, although uncontrolled, by Neri et al.[1] I definitely agree with their conclusion that this management

is a useful alternative to the traditional management of the third stage of labor, especially when fluid intake should be restricted or blood loss minimized.

As for the use of intraumbilical oxytocin for the management of the retained placenta, despite few reports that do not claim an advantage of the procedure,[2-4] I have no doubt in my mind that the properly timed intraumbilical injection of oxytocin is of great value in the management of the retained placenta.

Chestnut et al.[2] injected intraumbilical oxytocin if the placenta was not expelled in 5 minutes, which obviously is too short of an interval. Kristiansen et al.[3] have waited 20 minutes, which might still be too short of a waiting period before intervention. These authors have also used a smaller volume (10 ml) for the intraumbilical injection, which I believe is not enough to overcome the "dead space" in the umbilical cord and the placental vasculature. The hydraulic effect of the injected solution has its merits as it may in itself enhance placental separation by changing placental uterine interrelations. This principle was the basis for the Majon Gabastou maneuver, intraumbilical injection of 200 to 250 ml of physiologic solution, which was popular in the early 1930s in Europe when placental separation was delayed.[1] Haukson et al.[4] have waited as long as 60 minutes before intervention. It is possible that by increasing the waiting period some placentas otherwise defined as "retained" would be delivered. The 60-minute wait could have preselected the especially difficult cases (placenta accreta or increta), which could account for the relatively lower success rate (46%) and the reported longer injection-expulsion interval supports this assumption.

We all know that it was common practice in earlier days to wait an hour or even longer. However, today it is considered unwise to wait that long, exposing the parturient to the risks of increased third-stage blood loss and subsequent puerperal anemia. The risks of puerperal infections related to anemia and to puerperal blood transfusions should be continuously kept in mind.

Even in Kirstiansen's study 40% to 42% of the retained placentas could have avoided manual lysis under general anesthesia, which usually is the traditional management.[5]

In our hands the intraumbilical injection of oxytocin seems to be a very effective, quick, and safe method for the separation and delivery of the retained placenta. It has been successful in avoiding manual lysis under general anesthesia in more than 70% of cases.[5-7] I believe that oxytocin applied in this manner reaches the partially disrupted placental bed in a relatively higher concentration, stimulating uterine contraction and enhancing the cleavage of the placenta at the decidua spongiosa level. The hematoma that forms in this area further accelerates the process, and the placenta eventually separates and is delivered.

It seems that the injected solution may also have an hydraulic effect and may in itself contribute to placental separation by mechanical pressure as with the injection of saline solution alone. Thus the volume of the injected solution is of considerable importance. The timing of intervention is also of critical importance. It should not be too early and should not be unnecessarily delayed. I believe that the recommended waiting interval should be neither more nor less than 30 minutes. No maternal ill effects were reported even by the method's objectors, so why not use it when there is a chance to avoid manual lysis and general anesthesia, even if the success rate is not as high as in our experience?

Effects of selection bias on outcomes at referral centers

To the Editors:

Lubchenco et al. (Lubchenco LO, Butterfield LJ, Delaney-Black V, Goldson E, Koops BL, Lazotte DC. Outcome of very-low-birth-weight infants: Does antepartum versus neonatal referral have a better impact on mortality, morbidity, or long-term outcome? AM J OBSTET GYNECOL 1989;160:539-45) concluded that the better place to deliver a newborn weighing 500 to 1499 gm is a tertiary care referral center. They reported fewer fetal deaths, less neonatal morbidity, possibly a lower neonatal mortality, and better long-term outcome, when compared with results at the surrounding level I community hospitals. But their claims have been derived from a selected population at their referral center, not a stochastic one, as they have inferred by calling their study a total population-based one.

The authors were well aware of selection biases that distort reports of outcome at referral centers. All new-

borns delivered outside the center and who were referred in for care were excluded. This is a bias that can spuriously reduce mortality rates among very small newborns.[1] Furthermore, they have excluded all mothers who were transferred antenatally to the center for care, a source of selection bias that is controversial.

After these known sources of bias are excluded, a substantial distortion in the birth weight distribution of the infants remains. There were approximately 10,000 deliveries in the 4-year period under investigation.[2, 3] One half of these deliveries were excluded because the mothers were transferred antenatally for management of complications of pregnancy or impending problems of labor. Therefore the incidence rate of infants weighing 500 to 1499 gm in this study (145 infants born alive) was 2.9% or almost three times greater than the rate of a random distribution of newborns in this weight group, for Colorado or the United States.[4] Moreover, the 37% nonwhite mothers at the referral center, if all were black, could not account for a very-low-birth-weight rate of this magnitude.[4]

A possible explanation for the evident patient selection, suggested by Paneth et al.[5] but not investigated, is self-selection by the patients themselves. Referral centers have done their share of advertising; their existence in the community is advertisement itself. Women who anticipated very-low-birth-weight infant problems may have sought out the referral hospital. They also may have been better risks and better-motivated patients than the women in the general population. The subtleties of self-selection and motivation could be too elusive for statistical analysis. Nevertheless, the explanation is plausible too and should not be dismissed for the lack of quantifiable information.[6]

There remains a dimension of concern, perhaps more basic to perinatology. Reports from this particular referral center have served as a source of widely recognized reference data for predicting neonatal mortality rates in relation to birth weight and gestational age.[2, 7] The information and graphics in these reports have also been derived from a selected population, not an area-based, random population. Furthermore, as the rates of birth under 1500 gm increased from 2.3% of live births (1958 to 1968) to 3.9% of live births (1974 to 1980), indicating increased patient selection and potential selection bias, the mortality rate of this weight group declined. Antenatal transfers to the referral hospital also were included in these reports.

Reply

To the Editors:

Dr. Sepkowitz has addressed the numerous problems encountered in clinical research. Try as one can to control for variables, unexpected ones arise. Such was the case in this project when we discovered the large number of infants with birth weights of 500 to 1500 gm born to mothers who were transferred to the University of Colorado Health Science Center (UCHSC) for delivery because of obstetric problems.

Dr. Sepkowitz is quite astute in comparing our article with previously published data from our unit (his references 2 and 7). It gives me special pleasure to know that sufficient detail was presented in these publications to permit the comparisons and address the questions that he raised.

First of all, I wish to clarify a statement made in his opening paragraph. He writes that our data reported "possibly a lower neonatal mortality and better long-term outcome . . ." for infants born in the tertiary center. We did report that neonatal mortality was improved only in the *smallest* infants (i.e., <700 gm). There were *no* differences in overall long-term handicaps among the two populations.

The article by Koops et al. (his reference 2) gives mortality data on births at the University of Colorado Health Science Center over a 6-year period, from July 1974 to July 1980, to document the improved survival of infants in every birth weight and gestational age group. These data overlap the material published in our article, January 1975 through December 1978. Our article deals only with birth weights of 500 to 1500 gm while Koops' paper includes all births. The crucial piece of information that is lacking in the Koops data and ours is the birth weight distribution of infants born to the high-risk mothers referred to UCHSC for delivery.

I will attempt to provide this missing link from the figures available since Dr. Sepkowitz' figures and mine do not agree.

In paragraph 3, he notes (from Koops et al.) that there were approximately 10,000 deliveries during the 4-year period that we studied. This is correct. Then he states that "one half of these deliveries were excluded because the mothers were transferred antenatally for management of complications. . . ." This is not correct—*we* excluded half of the infants with birth weights 500 to 1500 gm because we knew that they were

Table I. Comparison of three reports by live births per year

	Lubchenco et al. (1972)	*Koops et al. (1982)*	*Lubchenco et al. (1989)*
Time of study (yr)	1958-1968	1974-1980	1975-1978
Population	All births; no maternal referrals	All births	Births 500-1500 gm; no maternal referrals
Length of study (yr)	10	6	4
Live births			
No.	16,287	14,413→	9,608 (based on 4 of 6 yr)
No./yr	1,629	2,402→	2,402
Births 500-1500 gm			
Total	298	538	145
No./yr	30 (1.84%)	90 (3.75%)	36 (1.5%*)

*If an equal number of infants from maternal transports were added to the 145 clinic live births (n = 290), the incidence of very low birth weight would be 3.0%.

maternal referrals. Only 5% of the 10,000 births in Koops' article were from maternal transfers. Koops et al. state that there was an increase in referral of high-risk mothers to the tertiary center "from 60 in 1974 to more than 150 in 1980."

I have expressed the numbers and percentages in live births per year from the three articles to which Dr. Sepkowitz refers (Table I).

A total of 5% of Koops' population of high-risk mothers would produce approximately 120 live-born infants per year. If the incidence of very low birth weight in the clinic population remained constant at 1.84%, as in 1958 to 1968, one would expect 44 infants on the basis of the increased number of deliveries. It is possible, and likely, that ≥46 of the 120 infants born to high-risk mothers would weigh between 500 and 1500 gm, giving an incidence in the UCHSC population of 1.91%.

Additional unpublished data show a rather constant number of births at UCHSC per year with birth weights 500 to 1500 gm up to 1973 and 1974 (n = 27 to 33 per year) during the years when few high-risk mothers were referred to UCHSC for delivery. In 1973 and 1974 the number of infants with very low birth weight more than doubled, to 75, and continued to rise, to 112, in 1979.

These figures do not support a global increase or a local increase in very low birth weight but, in my opinion, suggest an increased awareness of maternal high-risk problems and referral of mothers to tertiary centers for delivery of these infants.

There may be an effect on neonatal mortality when infants born to high-risk mothers are included. In fact, there was a slight but significant improvement in neonatal mortality in the referred group in our study (25% vs 37%).

Functional tolerance to the effects of ethanol on fetal biophysical activities?

To the Editors:

We read with great interest the case report by Castillo et al. (Castillo RA, Devoe LD, Ruedrich DA, Gardner P. The effects of acute alcohol intoxication on biophysical activities: a case report. Am J Obstet Gynecol 1989;160:692-3) concerning the effects of alcohol (ethanol) intoxication on fetal biophysical activities at 37 weeks' gestation. It is fascinating that fetal breathing activity persisted at near-normal levels when the maternal blood ethanol concentration was 322 mg/dl. The authors reported that the mother was admitted to the hospital on two previous occasions during this pregnancy for management of acute ethanol intoxication with similar maternal blood ethanol concentrations. The neonatal examination revealed facial anomalies consistent with the craniofacial dysmorphology of the fetal alcohol syndrome. These findings collectively are indicative of chronic maternal ingestion of excessive amounts of ethanol during gestation.

The pattern of fetal biophysical activities reported by Castillo et al. differs from the profile that we previously reported for maternal ingestion of a single, low dose of ethanol.[1] In our study of healthy pregnant women at 37 to 40 weeks' gestation, fetal breathing movements were virtually abolished by 30 minutes when the maternal blood ethanol concentration was maximal (33 mg/dl) and remained abolished for 3 hours, at which time maternal blood ethanol concentration was virtually nonmeasurable. This apparent discrepancy in the effects of ethanol on fetal breathing activity may be a result of the development of functional tolerance after repeated maternal consumption of ethanol.

We published the results of a study of near-term fetal sheep that showed that short-term maternal administration of moderate-dose ethanol resulted in the development of functional tolerance to the ethanol-induced suppression of fetal electrocortical and electroocular activities (after 7 days) and fetal breathing movements (after 14 days).[2] These findings are consistent with the observations in the case study of Castillo et al. However, the mechanism by which the mature fetus develops functional tolerance is not known.

In view of the fact that tolerance and physical dependence can develop in the adult during chronic ingestion of ethanol, it would be of interest to know whether the authors observed any withdrawal symptoms, including increased breathing activity, in the neonate. In this regard, it is noteworthy that the authors reported more than a twofold increase in breathing

incidence in the fetus when the maternal blood ethanol concentration decreased to <10 mg/dl; this is indicative of ethanol withdrawal in the fetus.

The authors speculate that their findings with regard to fetal breathing activity may have resulted from a transient metabolic acidosis or increased central nervous system levels of carbon dioxide in the fetus as a consequence of the acute ethanol intoxication. We have examined the effect of maternal administration of acute, high-dose ethanol on maternal and fetal arterial blood gases and acid-base balance in the near-term pregnant sheep.[3] There were no measurable changes in maternal and fetal blood gases and acid-base balance even at maternal and fetal arterial blood ethanol concentrations of 374 mg/dl and 382 mg/dl, respectively. On the basis of these data, it appears unlikely that a fetal acidosis occurred in the case reported by Castillo et al. Furthermore, to speculate that a transient fetal metabolic acidosis or increased central nervous system levels of carbon dioxide may have existed as a result of the metabolism of acetaldehyde, the proximate metabolite of ethanol, is scientifically incorrect. Acetaldehyde oxidation, catalyzed primarily by hepatic aldehyde dehydrogenase, leads to the formation of acetate. Increased reducing equivalents in the liver (i.e., nicotinamide adenine dinucleotide phosphate) and consequent reduction of pyruvate to lactate would have to occur to produce metabolic acidosis, and acetate would have to be oxidized by means of intermediary metabolism (i.e., tricarboxylic acid cycle) to produce carbon dioxide. Also, it has been well established that although maternal and fetal blood ethanol concentrations are virtually identical, the maternal and fetal blood acetaldehyde concentrations are about 1000-fold less than the respective ethanol concentrations, and the acetaldehyde concentration in fetal blood is less than that in maternal blood.[4,5] These pharmacokinetic data indicate that acetaldehyde has a minor role at best in the effects of maternal ethanol ingestion on the fetus.

These comments are intended to complement, not to detract from, the findings of this very interesting case report and especially the final conclusion drawn by the authors—that it is important to document maternal ethanol consumption when fetal biophysical activities are to be evaluated.

Reply

To the Editors:

We appreciate the interest of Drs. Smith, Patrick, and Brien in our case report, especially because their work on the effects of alcohol on the fetus is well known. With regard to the postnatal behavior, there was nothing noted in the baby's chart at birth to suggest withdrawal symptoms. The vital signs were stable and the overall behavior during the first 48 hours after birth was unremarkable.

With respect to the possible mechanisms responsible for the observed responses, it is interesting that although the authors of the letter find our theory scientifically invalid, reference 4 of their letter states that acute high-dose intake of alcohol can cause a transient collapse in the umbilical vasculature, resulting in fetal hypoxia and acidosis. Also, low levels of acetaldehyde in the fetal sheep circulation is not conclusive proof that acetaldehyde or its metabolites may not have a role in the pathogenesis of abnormal responses in the human fetus. Whereas tolerance to alcohol is a good explanation, the presence of fetal tachypnea and complete absence of fetal heart rate variability point toward an overall abnormal fetal response and not to an adaptive mechanism.

We look forward to the continuing work from this group of investigators in this area in which very little is known.

Blood sampling and transfusion in utero suggested in the pumping twin

To the Editors:

We read with great interest the article by Stiller et al. (Stiller RJ, Romero R, Pace S, Hobbins JC. Prenatal identification of twin reversed arterial perfusion syn-

drome in the first trimester. AM J OBSTET GYNECOL 1989;160:1194-6). Repeated ultrasonographic evaluation failed to reveal any sign of fetal congestive heart failure. Thus, the cord hemoglobin was 8.5 mg/dl at delivery and the infant died 3 days after birth. Unfortunately, the cause of death was not given. In accordance with the range of fetal hemoglobin concentration,[1] this fetus suffered from moderate anemia.

Van Allan et al.,[2] who reported the largest series of reversed arterial perfusion syndrome, noted that the main cause of morbidity and mortality of the pumping twin was congestive heart failure. Failure of ultrasonographic parameters to predict the severity of the anemia in rhesus isoimmunization was recently reported and fetal blood sampling was suggested in these cases.[3]

In light of this information we suggest that blood sampling of the pumping fetus should be taken and blood transfusion should be performed in utero if indicated to prevent fetal anemia and congestive heart failure.

Reply

To the Editors:

We appreciate the comments related to our article. It was suggested that fetal blood sampling be performed in the pump twin to assess for fetal anemia, with intrauterine transfusions to be performed if needed.

Unfortunately, little information exists in the literature as to the incidence of fetal anemia in twin reversed arterial perfusion pump babies. In the Van Allen et al. series of 14 pregnancies complicated by twin reversed arterial perfusion, no hemoglobin information is available.[1] A central question is whether the congestive heart failure that often occurs in pump fetuses is a result of the cardiovascular demands of supporting two circulations or whether it is a result of anemia.

Given the limited information concerning the fetal cardiovascular hemodynamics of the twin reversed arterial perfusion syndrome, the suggestion to perform fetal blood sampling is not unreasonable. It is hoped that further studies will document the value or lack there of in the management of this problem.

Lichen sclerosus, invasive squamous cell carcinoma, and human papillomavirus

To the Editors:

Invasive squamous cell carcinoma of the vulva appears to arise in association with a coexistent intraepithelial abnormality.[1] This abnormality usually falls into two main categories, either hyperplastic dystrophy, associated with lichen sclerosus in most cases, or severe atypia grade 3 (vulvar intraepithelial neoplasia). Controversy exists over the malignant potential of lichen sclerosus, with studies demonstrating the coexistence of lichen sclerosus in excision specimens of squamous cell carcinoma ranging from little or no association[2] to 63%.[3] In our own series of 78 cases of squamous cell carcinoma the histologic coexistence with lichen sclerosus was 60%. Conversely, however, in clinical practice this relationship is small as we examine and treat a large number of patients with lichen sclerosus, few of whom subsequently develop a squamous cell carcinoma.[3, 4] This discrepancy may reflect the beneficial effects of treatment as the majority of cases of lichen sclerosus recognized histologically in the squamous cell carcinoma specimens had not been diagnosed or treated previously. Alternatively, the difference may indicate the prerequisite of a cofactor such as concurrent infection with human papillomavirus (HPV). To test this hypothesis we analyze 10 cases of squamous cell carcinoma with coexistent lichen sclerosus to determine the presence of HPV. The technique used for detection of the virus was Southern blot hybridization under stringent conditions. Table I indicates the probes used and the results.

The negative findings suggest either that the viral deoxyribonucleic acid tested was not present or that insufficient total deoxyribonucleic acid was available for detection in the tissues sampled. The latter explanation seems unlikely as we had conducted simultaneously an analysis with the same technique on 10 cases of squamous cell carcinoma with evidence of grade 3 vulvar intraepithelial neoplasia; we obtained positive results in seven of the 11 lesions (Lessana-Leibowitch M. Unpublished data), and in six of seven HPV #16 was detected.

Table I. HPV deoxyribonucleic acid sequences in squamous cell carcinoma of vulva with coexistent lichen sclerosus

Probe	*Detection*
HPV 16	0/10
HPV 18	0/10
HPV 31	0/10
HPV 33	0/10
HPV*	0/10

*Undetermined type.

A recent study of five cases of uncomplicated lichen sclerosus failed to demonstrate the presence of HPV.[5] These preliminary results suggest that HPV is not implicated in the etiology of lichen sclerosus or in the induction of malignant change in this disorder.

Measurement of unconjugated estriol by enzyme-linked immunosorbent assay fails to show an association with Down syndrome

To the Editors:

Canick et al.[1] and subsequently Wald et al.[2] have reported on the use of unconjugated estriol as a marker for Down syndrome in a protocol of prenatal maternal serum screening. Their reports indicate that maternal serum levels of unconjugated estriol are significantly lower in pregnancies affected by Down syndrome than in matched controls. Any marker that adds to detection efficiency in prenatal Down syndrome screening, would be particularly welcome. The poor performance of maternal serum α-fetoprotein as a marker for Down syndrome has been reported.[3-5]

Table I. Levels of unconjugated estriol in 27 cases of trisomy 21

Rank	*Gestational age (wk)*	*MoM*
1	18	0.4
2	18	0.4
3	16	0.64
4	17	0.64
5	15	0.68
6	15	0.68
7	15	0.69
8	17	0.8
9	14	0.82
10	16	0.86
11	16	0.87
12	16	0.95
13	17	1.04
14	15	1.09
15	15	1.1
16	16	1.15
17	18	1.15
18	15	1.16
19	16	1.39
20	18	1.51
21	16	1.82
22	16	2.31
23	16	2.47
24	16	2.57
25	15	2.8
26	16	2.94
27	16	3.79

Table II. Percent of Down syndrome cases and controls with maternal serum unconjugated estriol levels less than or equal to given MoM levels

Unconjugated estriol level (MoM)	*Down syndrome cases (%)*	*Controls (%)*
≤0.50	7.4	4.7
≤0.65	14.8	19.4
≤0.80	29.6	36.5
≤1.00	44.4	51.3

Our first evaluation[6] of unconjugated estriol used the same radioimmunoassay reagents and procedure (modified per Canick et al.[1] and Wald et al.[2]), but did not show the utility of this marker. No significant difference was found in the level of unconjugated estriol between controls and pregnancies affected by Down syndrome.

We have completed a further study of unconjugated estriol with the use of a different method of measure-

ment, enzyme-linked immunosorbent assay (ELISA). Table I shows unconjugated estriol values as determined by ELISA in 27 documented cases of trisomy 21 relative to 515 controls matched for gestational age, maternal age, and freezer storage time. In addition, all samples were from white, nondiabetic, singleton pregnancies. This second study does not show a reduction in the level of unconjugated estriol in Down syndrome cases. Indeed, on average, the unconjugated estriol value in Down syndrome cases (median multiple of the median [MoM]* = 1.09) is higher than in controls (median MoM = 0.99). This data is particularly striking in light of the fact that levels of unconjugated estriol in controls, established with ELISA, range from 1.2 to 2.5 ng/ml during weeks 14 to 18 of gestation and are similar to radioimmunoassay data previously reported during this stage of pregnancy. Table II shows that the distributions of maternal serum unconjugated estriol levels in pregnancies affected by Down syndrome and controls overlap to such a degree that discrimination becomes impractical.

The results of this study suggest that maternal serum unconjugated estriol evaluation by ELISA as an additional marker in a Down syndrome screening protocol will reduce detection efficiency because the unexpected higher levels of this analyte in cases of Down syndrome would artificially reduce risk. The fact that unconjugated estriol when measured by different clinical laboratory techniques fluctuates about 1 MoM in Down syndrome cases provides no support for the hypothesis that the unconjugated estriol analyte is a marker for Down syndrome. We recommend against the use of unconjugated estriol within a prenatal Down syndrome screening protocol.

Fructosamine in gestational diabetes

To the Editors:

We read with great interest the article by R. Comtois et al. (Comtois R, Desjarlais F, Nguyen M, Beauregard H. Clinical usefulness of estimation of serum fructosamine concentration as screening test for gestational diabetes. AM J OBSTET GYNECOL 1989;160:651-4).

Glycosylated serum proteins, measured as fructosamine, have been used for several years as an index of short-term control of diabetes mellitus, often in conjunction with glycosylated hemoglobin, which measures medium to longer-term control.

In the diagnosis and management of gestational diabetes it is essential to have an index of short-term hyperglycemia because this condition may not develop until late in pregnancy. Roberts et al.[1,2] have proposed that fructosamine can be used as a screening test for gestational diabetes and on theoretic grounds this would seem to have some distinct attractions, particularly because that fructosamine should reflect the extent of hyperglycemia in patients on their normal diet rather than under the very artificial conditions of a glucose tolerance test (GTT).

To examine this proposition we examined the relationship between serum fructosamine and GTT results in 161 successive patients given GTTs at 30 weeks' gestation. These patients were selected for a GTT on the basis of a screening test given to all antenatal patients. Positive screening test results consisted of a plasma glucose level >8.1 mmol/L 1 hour after a 75 gm glucose load taken in the nonfasting state at 28 weeks' gestation.

The GTT procedure consisted of capillary whole blood glucose measurement (YSI glucose analyzer, Yellow Springs Instrument Co., Yellow Springs, Ohio) before, 1 hour after, and 2 hours after ingestion of a 100 gm load taken after an overnight fast. The criteria for an abnormal glucose value were fasting >5.0, 1 hour >9.5, and 2 hour >8.1 mmol/L. Fructosamine was also measured on the fasting sample with the Roche kit on a Cobas FARA analyzer (F. Hoffmann-La Roche Ltd., Basel). The between batch precision was 3% and 6% at levels of 1.72 and 3.50 mmol/L, respectively.

The results shown in Table I indicate that there is no significant difference in fructosamine levels in women with gestational diabetes, as compared with normal women. This result indicates that serum fructosamine is of no value in either the diagnosis or the monitoring of management of diabetes in pregnancy.

Table I. Fructosamine levels in relation to oral GTT

Results	No.	Fructosamine (mmol/L)		p Value
		Mean	SD	
Normal	116	2.04	0.19	—
Elevated				
1 hour only	13	2.06	0.21	>0.7
2 hours only	9	2.02	0.12	>0.8
1 and 2 hours	23	2.07	0.28	>0.4

abetes by the week 30 of pregnancy may reflect the mildness of the hyperglycemia in this condition and the shortness of duration of the glucose intolerance.

These results are very similar to those reported by Comtois et al. desite the fact that they were reporting on patients examined because of clinical risk of gestational diabetes, whereas our study looked at a group selected on the basis of a screening test applied to a total antenatal population.

Therefore the situation remains that until some better test is available the only reliable method to detect patients at risk of gestational hyperglycemia is to perform an oral GTT at 28 to 30 weeks' gestation.

Reply

To the Editors:

We are pleased to see that Doery et al. were interested in our article and even performed a study of the clinical usefulness of serum fructosamine as a screening test for the total antenatal population.

The results observed by Doery et al. are similar to ours, despite the fact that the fructosamine screening test was applied in a "less selected" population. However, the study did not report the results on their pregnant patients of serum fructosamine levels corrected for the protein concentration, which according to our data improves the sensitivity of this test.

In our study the difference between the serum fructosamine concentrations of the women with gestational diabetes and the pregnant women with normal glucose tolerance test results, even when expressed in a more sensitive form such as the fructosamine/protein ratio (39 ± 3.9 μmol/gm versus 37 ± 3.2 μmol/gm, $p < 0.05$), was statistically less significant than the difference between their fasting serum glucose levels (107 ± 13.7 mg/dl versus 82 ± 8.6 mg/dl, $p < 0.001$). The first explanation is that the sensitivity of fructosamine is too low to detect a difference in the mean daily blood glucose level of approximately 30 mg/dl between the two groups. In our study the mean daily blood glucose level of our patients with gestational diabetes was 122 ± 27 mg/dl. These results also could be explained, at least in part, by the fact that during the few weeks before the diagnosis the usual mean glucose level in patients with gestational diabetes on spontaneous diet was just slightly higher than that in normal pregnancy; consequently, the increase in fructosamine level was usually not large enough to be clinically useful. Another explanation could be that patients with gestational diabetes had a lower caloric intake than that of normal pregnant patients. Because we observed a good correlation between serum fructosamine/protein ratio and spontaneous caloric intake ($r = 0.72$, $p < 0.005$), the fructosamine level of the patients with gestational diabetes could be relatively decreased by this lower caloric intake. However, additional studies that quantify more precisely the spontaneous diet in normal pregnant patients and in patients with gestational diabetes are needed before any definitive conclusions can be drawn about the results of a possible difference in the spontaneous diet of these two groups of patients with regard to fructosamine levels.

Blood gas studies in fetal heart blood

To the Editors:

I enjoyed the article by Westgren et al. (Westgren M, Selbing A, Stangenberg M, Phillips R. Acid-base status in fetal heart blood in erythroblastotic fetuses: a study with special reference to the effect of transfusions with adult blood. AM J OBSTET GYNECOL 1989;160:1134-8) and note that several of the changes they report in fetal

blood gas and acid-base status in response to anemia and transfusion of adult blood were similar to our findings.[1, 2] However, their use of blood obtained from the fetal heart and imperfect statistical analysis may explain the differences from our results.

Fetal heart blood is a mixture of blood from the ductus venosus, upper and lower parts of the body in descending order of oxygenation. Streaming of blood within the heart is thought to minimize mixing and so the blood gas results would depend on the exact site of sampling, even within a chamber of the heart. Their statement "the primary target for the puncture was the left ventricle" suggests that sometimes the blood was obtained from other chambers. Therefore, at the very least they need to publish control data for heart blood from fetuses without erythroblastosis. As they state in the article they also need to investigate changes with gestational age because these are important in cord blood[3] and our data analysis corrected for this factor.

Westgren et al. found no fall in pH or rise in base excess in the heart when fetuses had adult blood in their circulation, whereas our study found these changes in umbilical arterial blood. The most likely explanation for this difference is that heart blood is a mixture of umbilical arterial and venous blood so abnormalities we found in the former were not detected.

Finally, their data were 70 observations from 26 fetuses, whereas ours were 80 observations from 80 fetuses. This means that they included multiple observations from some pregnancies and the data were not independent as required for multivariate analysis.

Reply

To the Editors:

We wish to refute the challenge of Dr. Soothill that the difference between our results and theirs is because of "imperfect statistical analysis." Before use of a multivariate analysis, stratification was performed for dependent observations in our study so the statistical analysis does not explain the discrepancy between our two studies.

A more likely explanation is that different sites were used to obtain fetal blood. We studied mixed venous and arterial blood, whereas Soothill et al. studied pure umbilical artery blood. It is not surprising that these two puncture sites differ in respect to studied parameters.

Finally, although the study by Soothill et al. included 80 observations, they based their analyses in respect to umbilical artery blood on 13 pairs, 26 observations, which is a rather limited number to achieve a high degree of confidence ($p < 0.036$).

Active management of labor

To the Editors:

I have been studying active management of labor as described by O'Driscoll and Meagher[1] in connection with the preparation of my master's thesis in nursing at the University of Washington. I have just read the latest response by Leveno et al.[2] to O'Driscoll et al.[3] in the continuing repartee between Dallas and Dublin. A few thoughts and questions have occurred to me concerning the merits of the active management protocol, and the challenge to them put forth by Leveno et al.[2]

The effect that active management has on several of the outcome variables of labor has been measured by researchers among different populations. In Canada, Akoury et al.[4] compared a sample of 552 normal nulliparous women delivered of infants in accordance with the system of active management with 553 similar control subjects managed with routine care. Turner et al.[5] studied a multiracial sample of 1000 nulliparous patients whose labors were actively managed, and Sheehan[6] compared the records of 569 low-risk nulliparous patients from the National Maternity Center in Dublin, where active management is practiced, with 471 similar patients who were delivered of infants in a hospital in the United States. The findings of these three groups of investigators included decreased rate of cesarean section, length of labor, and rate of forceps delivery among the actively managed parturients, with no increase noted in perinatal morbidity or mortality. These results would indicate, as Turner et al.[5] stated, ". . . active management can be safely applied outside Ireland to reduce the incidence of Caesarean childbirth."

From a nursing perspective, other studies also add an interesting dimension to the active management debate. Research conducted by the pediatricians Klaus et al.[7] and Kennell et al.[8] has evaluated one component of active management, that of constant supportive companionship for the laboring patient. With no changes in medical care, these researchers have found in controlled, randomized trials that the constant presence of a reassuring female companion for the woman has produced statistically significant reductions in the rate of

cesarean section, duration of labor, and perinatal complications. Their results were comparable to the effects of active management of labor as measured by O'Driscoll and Meagher.[1] O'Driscoll and Meagher[1] have written, "Strict limitation of the duration of labor and continuous personal attention throughout are considered to be the basic requirements on which a high standard of care depends . . . neither is possible without the other." Could it be that the constant supportive and individualized nursing care practiced in active management is in large part responsible for its beneficial effects on the outcome of labor?

I await with interest the reply from Dublin to the report of Leveno et al.[2] If, after the results are in, active management does not fulfill its promises, this debate has at least encouraged a critical appraisal of the high cesarean section rate in the United States. Women in this country are perhaps due a reasoned and well researched justification for the frequent use of this procedure.

Reply

To the Editors:

We are delighted with Nurse Lynch's letter concerning our report on cesarean section. Nurse Lynch correctly emphasizes that "constant supportive and individualized nursing care" is undoubtedly pivotal in good obstetric care. However, we are reluctant to broaden the cesarean rate debate to allegations about superiority (or inferiority) of nursing on two continents. Indeed, we are prepared to rise up for our own nurses!

We too are of the view that "women in this country are . . . due a reasoned and well researched justification of the frequent use of this procedure (cesarean)." We believe this sentiment has fueled our participation in the debate. Our purpose has not been to defend abuse of cesarean section but instead to encourage its prudent use.

Subspecialty of gynecologic oncology proposed to manage breast disease

To the Editors:

I read with great interest the article by Dr. Norbert Gleicher (Gleicher N. Breast disease programs in obstetrics and gynecology: a plea for training in mammography. AM J OBSTET GYNECOL 1989;161:267-70). His point that the gynecologist most often faces breast disease and should be familiar with mammography is excellent. I would like to take his suggestion one step further.

It is disconcerting to the patient to be seen by different physicians for the detection, diagnosis, and treatment of breast disease. When a malignancy is detected, the patient is often treated not only by a surgeon but also by a medical oncologist and a radiotherapist. Inasmuch as the breast is a reproductive organ, I suggest that the subspecialty of gynecologic oncology have a role in the care of the patient with breast cancer. In this subspecialty the physician is trained in the detection of malignancy and coordinates the surgical, medical, and radiotherapeutic management. I believe this goal could be accomplished by incorporating training in the management of breast cancer into fellowship programs.

Although this concept would represent a major change in the present approach to women with breast cancer and will certainly encounter resistance and criticism, I suggest a pilot program be established at several centers to evaluate the role of the gynecologic oncologist in the treatment of this disease. Ultimately I believe the care of women will be improved by such action.

Placental siderosis in maternal β-thalassemia

To the Editors:

Whereas the article by Birkenfeld and coworkers (Birkenfeld A, Mordel N, Okon E. Direct demonstration of iron in a term placenta in a case of β-thalassemia major. AM J OBSTET GYNECOL 1989;160:562-3) is of interest, such placental deposits of stainable iron have

long been recognized in the absence of maternal hemoglobinopathy. They form part of the spectrum of normal placental maturation and senescence from the ninth gestational week onward.[1] Basement-membrane siderosis alone, even in the setting of maternal β-thalassemia, is not necessarily a significant finding, and the statement of Birkenfeld and coworkers that "positive (iron) staining in the placental villi probably reflects tissue ferritin and hemosiderin deposits *that prevent excessive iron transport to the fetus*" (emphasis added) is not justified by the data presented.

Normal values for placental iron content[2] and for levels of iron, ferritin, and transferrin saturation in term infant umbilical cord blood[3] have been defined. Were placental concentrations of iron determined for the pregnancy in question? Was evidence of iron loading sought in the infant? These data might provide valuable information about the regulation of maternofetal iron transport in the presence of maternal hypersideremia.

A. S. Knisely, MD

Department of Pathology
University of Utah Medical Center
Salt Lake City, UT 84132

Reply

To the Editors:

We thank Dr. Knisely for his comments. Publications that describe transferrin and ferritin in the human placenta have applied immunohistochemical methods for the detection of these substances.[1,2,3] McKay et al.[4] have stated that "during the third trimester there is a progressive diminution in the amount of iron deposited in the placental stroma. The subtrophoblastic deposits noted in the second trimester have *all but disappeared.* A few villi in many term placentas however contain one to several *macrophages* (Hofbauer cells) which contain ferric but not ferrous iron."

We have used the Gomori Prussian blue reaction to detect hemosiderin in normal term placentas and were unable to visualize stainable iron in the stroma of the chorionic villi. However, we did show it in the term placenta from a mother suffering from β-thalassemia major.[5] It is known that with normal iron stores only trace amounts of hemosiderin are found in the body, mainly in reticuloendothelial cells in the bone marrow, spleen, and liver. In iron-overloaded cells, most of the iron is stored in the form of hemosiderin. The Prussian blue reaction that we have used might not visualize very small amounts of ferritin in the placental villi, whereas sensitive immunohistochemical methods will do so.

We believe that taken together, these observations do imply a difference of placental iron load between the normal placentas and the placenta of the thalassemic mother. Although we have not examined the ferritin level in the cord blood, the mere observation of hemosiderin deposits in the placenta of the thalassemic mother probably reflects iron deposits that could have otherwise been transferred to the fetal circulation.

Significance of uric acid clearance in preeclampsia

To the Editors:

Although serum uric acid level is useful for estimating the severity of preeclampsia,[1] the level of serum uric acid often overlaps between preeclampsia and normal pregnancy.[2] Decrease in uric acid clearance in preeclampsia has been known,[3] but its use in the precise evaluation of preeclampsia has not been reported. We estimate the usefulness of uric acid clearance in various conditions of pregnancy.

A total of 33 pregnant women (normal pregnancy, 12; preeclampsia, 10; normal pregnancy with chronic glomerulonephritis, 6; superimposed preeclampsia, 5) were studied. Ages of patients ranged from 23 to 39 years. All clinical and laboratory data were obtained from 38 to 40 weeks' gestation and all patients were delivered of infants at 39 to 40 weeks' gestation.

There were no significant differences in serum creatinine levels (normal pregnancy, 0.81 ± 0.02 mg/dl; preeclampsia, 1.00 ± 0.09 mg/dl; normal pregnancy with chronic glomerulonephritis, 1.14 ± 0.09 mg/dl; superimposed preeclampsia, 1.48 ± 0.23 mg/dl; mean ± SEM) or creatinine clearance (normal preg-

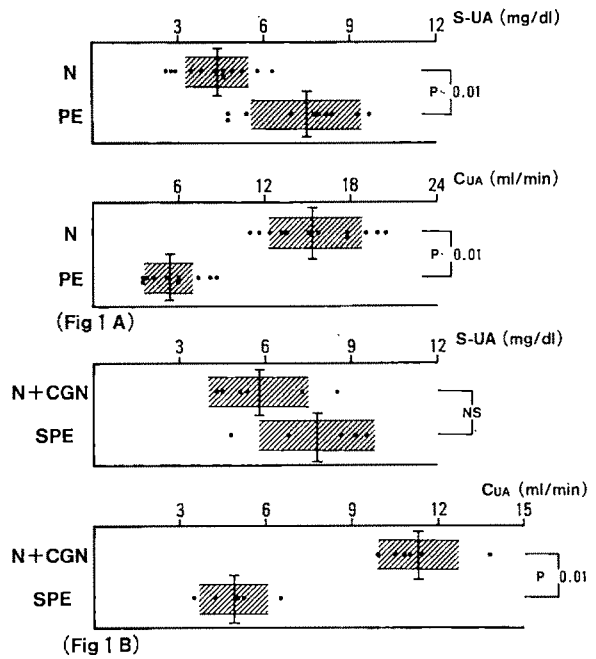

Fig. 1. A, Serum uric acid concentration *(S-UA)* and uric acid clearance *(CUA)* in normal pregnancy *(N)* and preeclampsia *(PE)*. **B,** Serum uric acid concentration *(S-UA)* and uric acid clearance *(CUA)* in normal pregnancy with chronic glomerulonephritis *(N + CGN)* and superimposed preeclampsia *(SPE)*. *Bars* show mean and *shadowed areas* show ±SD.

nancy, 148.7 ± 10.2 ml/min; preeclampsia, 121.4 ± 9.3 ml/min; normal pregnancy with chronic glomerulonephritis, 124.3 ± 14.1 ml/min; superimposed preeclampsia, 95.0 ± 17.2 ml/min). Although the serum uric acid level in preeclampsia (7.5 ± 0.61 mg/dl) increased significantly ($p < 0.01$) compared with that of normal pregnancy (4.4 ± 0.32 mg/dl), this index failed to differentiate preeclampsia from normal pregnancies because of overlap between individual cases in the two groups. On the other hand, these two conditions were clearly distinguished ($p < 0.01$) by uric acid clearance (normal pregnancy, 15.3 ± 0.95 ml/min; preeclampsia, 5.4 ± 0.54 ml/min) that was determined from 24-hour urine collection at the patient's house (Fig. 1, *A*). In pregnant women with chronic glomerulonephritis there was no significant difference in serum uric acid levels between normal pregnancy with chronic glomerulonephritis (5.8 ± 1.70 mg/dl) and superimposed preeclampsia (7.8 ± 0.89 mg/dl). However, uric acid clearance significantly decreased in superimposed preeclampsia (4.9 ± 0.54 ml/min) compared with normal pregnancy with chronic glomerulonephritis (11.3 ± 0.57 ml/min) ($p < 0.01$), and there was no overlap between these two groups (Fig. 1, *B*).

There was significant positive correlation between uric acid clearance and infant birth weight ($r < 0.81$, $p < 0.05$), and negative correlation with mean blood pressure ($r = 0.84, p < 0.01$) in both normal pregnancy and preeclampsia. The birth weight and mean blood pressure during gestation are currently accepted as markers for estimation of the severity of preeclampsia.

In conclusion, although there is no conclusive explanation for a decrease in uric acid clearance in preeclampsia,[4,5] it is one of the most reliable markers for the diagnosis and estimation of the severity of preeclampsia. This index is also useful in the differentiation of superimposed preeclampsia from normal pregnancy with chronic glomerulonephritis.

Vaginal ultrasonography in the diagnosis of ectopic pregnancy

To the Editors:

We read with interest the article by Dr. Timor-Tritsch et al. (Timor-Tritsch IE, Yeh MN, Peisner DB, Lesser KB, Slavik BA. The use of transvaginal ultrasonography in the diagnosis of ectopic pregnancy. AM J OBSTET GYNECOL 1989;161:157-61) on vaginal ultrasonography in the diagnosis of ectopic pregnancy. It is an excellent addition to the literature on this subject; however, we have a few comments.

The authors state that the visualization of an intrauterine gestation rules out the possibility of an ectopic pregnancy. In 1948 DeVoe[1] initially calculated the incidence of heterotopic pregnancy by multiplying the incidence of fraternal twinning by the incidence of ectopic pregnancy, arriving at the generally quoted figure of 1 in 30,000 pregnancies. Since that time, the incidence of both multiple gestations and ectopic pregnancies has risen (as a result of assisted reproductive technologies, pelvic inflammatory disease, etc.) and the actual incidence of heterotopic pregnancy has been reported to be 1 in 2600 births.[2] Whereas even this number makes the likelihood of finding a heterotopic pregnancy unlikely, if the ultrasonographer does not routinely look for a tubal gestation, even in the presence

of an intrauterine one, there is little chance of making a preoperative diagnosis of an unruptured ectopic pregnancy. This is especially important because the incidences quoted are in a general pregnant population and thus the likelihood of a heterotopic pregnancy is even greater in a symptomatic woman first seen in an emergency room.

The authors noted that all their ruptured ectopic pregnancies had some free pelvic fluid visualized by ultrasonography. Whereas they also state that variable amounts of fluid were noted with unruptured ectopic gestations, the impression left is that fluid noted on ultrasonographic scan is a significant sign of possible tubal rupture. Although fluid in the cul-de-sac should increase the index of suspicion for an ectopic pregnancy, there are two important caveats. First, there are false-positive culdocenteses (ruptured corpus luteum cyst) that clinically mimic an ectopic pregnancy and would also have fluid in the cul-de-sac noted on ultrasonographic examination, thus limiting the specificity of this finding. More importantly, institutions vary in their aggressiveness in attempts to manage an ectopic pregnancy laparoscopically (as evidenced by 45 of 49 patients in this article undergoing laparotomy), and many flow sheets for management of suspected ectopic pregnancies will bypass laparoscopy in favor of laparotomy if there is evidence of tubal rupture. It follows that patients with fluid noted on examination, who otherwise might be candidates for a laparoscopic approach, would be managed with laparotomy if this finding is not put into perspective. Whereas fluid is an important variable and should raise one's index of suspicion for tubal rupture, the literature reports a positive culdocentesis with as many as 65% to 77% of unruptured ectopic pregnancies.[3, 4]

Finally, we wish to congratulate the authors for their excellent clinical study.

Reply

To the Editors:

We thank Drs. Frishman and Luciano for their comments. They are correct with regard to the possibility of a heterotopic pregnancy and the importance of scanning the adnexa even if an intrauterine pregnancy is evident. This fact has been stressed and restressed in almost all articles on the subject of transvaginal techniques. However, we opted not to deal with this subject although it is a valid observation.

With regard to the presence of fluid in the cul-de-sac in cases of apparently nonruptured or even live tubal gestations, we have the following response.

As inferred by the article, it seems to us that it is very difficult to differentiate a ruptured tube from an unruptured one that is merely leaking blood. We have observed blood leakage in several cases of live and clearly unruptured tubal pregnancies. However, the remarks of Drs. Frishman and Luciano are accurate when they state that the presence of cul-de-sac fluid should arouse the suspicion of a tubal pregnancy. Transvaginal sonography has the ability not only to detect small amounts of fluid but also to image floating particulate matter. This combination in a patient with a clear tubal ring or positive serum β-subunit of human chorionic gonadotropin is indicative of the presence of blood in the pelvis. Consequently, culdocentesis is a superfluous procedure in offices or institutions in which transvaginal sonography is available. It is also more specific and more sensitive than culdocentesis in the diagnosis of pelvic fluid.

From our experience we can make the following observations: (1) the presence of blood in the pelvis is not indicative of the type of ectopic pregnancy; (2) a live tubal ectopic pregnancy may coexist with some blood in the pelvis; (3) a larger amount of pelvic blood is usually indicative of a ruptured ectopic pregnancy or a bleeding tubal abortion; and (4) it seems to be difficult to differentiate between a tubal abortion and a tubal rupture.

Physician characteristics and cesarean delivery

To the Editors:

The retrospective study by Berkowitz et al. (Berkowitz GS, Fiarman GS, Mojica MA, Bauman J, Haynes de Regt R. Effect of physician characteristics on the cesarean birth rate. AM J OBSTET GYNECOL 1989; 161:146-9) was of interest because of recent personal experiences during the past 2 years at the National Maternity Hospital, Dublin, Ireland. The authors suggest that the observed differences in the cesarean birth rate may be explained by physician characteristics. It is tempting to consider that the trend of a rising cesarean delivery rate is, in part, physician related.

Whereas the validity of rate comparison in different obstetric populations can be questioned, the disturbing

trend of rising cesarean rates has not been observed in Dublin, despite many changes in physician staff.[1,2] In an effort to understand these varying rates the following fundamental concepts must be addressed before "physician characteristics" can be considered: (1) the cesarean sections in nulliparous and multiparous patients must be analyzed separately, (2) primary and repeat cesarean sections should be distinguished, and (3) whether the patient was in labor or not must be recorded. Daily documentation of all cesarean sections, weekly peer review of all cesarean deliveries in nulliparous patients in labor, and monthly review of all cesarean deliveries form an essential prospective audit of obstetric practice in Dublin. Hence the problem of having approximately 10% of cesarean sections without a clear indication does not arise in that institution. The management of labor in the National Maternity Hospital applies to all patients—private and nonprivate. It is these characteristics that are central to the understanding of cesarean birth rates.[3]

Reply

To the Editors:

Although we agree that such factors as nulliparity, a previous cesarean section, and, to a lesser extent, presence of labor are important determinants of cesarean birth rates, it is unlikely that these factors account for the more than fourfold increase in the rate of cesarean deliveries during the past two decades in the United States. Other contributing reasons also suggested include the improved safety of cesarean procedures for the mother, the increased use of cesarean sections for breech presentations and low-birth-weight fetuses, higher proportions of older primiparous patients, improved third-party reimbursement, and fear of malpractice,[1,2] but some of these factors remain speculative.

Recent studies have also shown that rates of cesarean sections differ between private and clinic patients[3] as well as by socioeconomic status.[4] We also observed that there are large variations in the cesarean section rate among individual physicians caring for private patients at our institution. Thus, we were interested in examining whether these variations could be attributed to such physician characteristics as age, years of experience, gender, and practice setting (solo versus group setting).[5]

It appears reasonable to conclude that there are multiple factors that have led to the dramatic increase in cesarean section rates in the United States. Identification of these factors serves as a first step for establishment of appropriate educational and monitoring programs to safely reduce the current rate of cesarean section.

Intrauterine growth retardation is not the same as small for gestational age

To the Editors:

I do not agree with Goldenberg et al. (Goldenberg RL, Cutter GR, Hoffman HJ, Foster JM, Nelson KG, Hauth JC. Intrauterine growth retardation: standards for diagnosis. AM J OBSTET GYNECOL 1989;161:271-7) that much of the confusion that presently surrounds intrauterine growth retardation (IUGR) would be eliminated if their recommendations were followed. Indeed, I believe the opposite because they are not discussing a definition of IUGR but rather are defining small-for-gestational-age (SGA) newborns.

Wilcox has mentioned several reasons for not confusing SGA with IUGR.[1] These include:

1. IUGR is probably not confined to the smallest 10% as are SGA newborns
2. SGA infants are a heterogeneous group that includes those who appear normal except for their small size
3. Multiple factors cause a symmetric distribution of term newborn weights. By implication, newborns at extreme weight occur in the absence of pathologic factors and the occurrence of SGA newborns is not preventable
4. IUGR and SGA are two separate concepts

To believe that IUGR is the same as SGA, suggests that at least 10% of fetuses have an unfavorable intrauterine environment. This concept causes a waste of

obstetric resources and patient time, and increases the rate of obstetric interference.

The obstetric signs of an IUGR fetus include indication of relative maternal hypovolemia (hemoconcentration), dysmaturity, oligohydramnios, chronic fetal distress (abnormal biophysical monitoring), and most of all, "a falling off the growth curve."[2] It is hoped that obstetricians will leave the normal SGA fetus alone and will concentrate on treating or rescuing the IUGR fetus.

Reply

To the Editors:

It appears from his letter that Dr. Goodlin wants, not only us, but all who write in the obstetric literature to use the term small for gestational age (SGA) to describe those babies who weigh less than the tenth percentile birth weight for gestational age and to use intrauterine growth retardation (IUGR) to describe the fetus that is associated with maternal hemoconcentration, dysmaturity, oligohydramnios, and chronic fetal distress. He may wish it, but most authors who write in the obstetric literature today do not agree, and define IUGR as less than the tenth percentile birth weight for gestational age. Therefore, in our use of the term *IUGR* we adhered to the common usage. Most important, in this article we very carefully defined the condition under discussion as birth weight for gestational age less than the tenth percentile.

We do happen to agree with Dr. Goodlin that all babies who weigh less than the tenth percentile for gestational age, whether they are called IUGR or SGA, are a heterogenous group that often includes some infants who appear normal except for their small size. We also would agree with him that there are infants outside the tenth percentile who apparently have the genetic potential to be larger, but because of environmental or other factors do not reach their full growth potential. We also would agree with Dr. Goodlin that "It is hoped that obstetricians will leave the normal SGA fetuses alone and will concentrate on treating or rescuing the IUGR fetus."

Nevertheless, whereas it would be very nice to know each infant's ultimate potential for growth and then to compare this potential to the growth actually attained, deriving such data is problematic at best. However, as a first step we thought it would be important for a uniform standard to define the tenth percentile to be used from study to study. We stand by our suggestion that the development of a concensus on the birth weight used to define the tenth percentile birth weight at each gestational age would *decrease,* not increase confusion. Until one can agree on a practical definition of the "extremes" of birth weight, there is not even a starting point to discuss with other investigators the proportion of those infants "at extreme weight" who may be normal or abnormal, or to define the risk factors for and the ultimate outcomes associated with reduced fetal growth.

Calculation of ritodrine half-life

To the Editors:

I read with interest the informative report of Dr. Caritis et al. (Caritis SN, Venkataramanan R, Cotroneo M, Chiao J-P. Pharmacokinetics of orally administered ritodrine. AM J OBSTET GYNECOL 1989; 161:32-5) and agree with the authors that the plasma concentrations of ritodrine suggest that the maximal dose for oral administration should be increased. However, I am interested in the methods used in the calculation of the half-life (Table II). The authors present a half-life of ritodrine of 166 minutes in fed patients. However, the peak level of 8.3 ng/ml at 78 minutes and level of 1.7 ng/ml at 240 minutes would suggest a greater than fourfold decrease in 162 minutes. A similar study of oral ritodrine pharmacokinetics[1] indicated an initial half-life of 1.2 hours and a second phase half-life of 14 hours.

There are many difficulties in determining half-life after a single oral administration, including the precise detection of the time of peak drug concentration, the continued absorption of the drug throughout the decay period, and the appropriate modeling of the clearance pathways.[2] Would the authors please provide additional information with regard to their methods of calculation?

Reply

To the Editors:

Dr. Ross raises two questions. First, he questions why the decrease in ritodrine concentration from the peak value appears to be more rapid than expected if the half-life of the drug was 166 minutes. He also asks how we calculated the half-life because our value differs from what has been previously published.[1]

After ritodrine is absorbed, it is distributed to extravascular sites. Plasma concentrations decrease rapidly during this distribution phase. After distribution is complete, plasma concentrations decrease slowly. This disposition phase reflects ritodrine metabolism or excretion.[2] The clinically pertinent half-life is the one obtained during the disposition phase. In this study, we used noncompartmental methods to calculate the disposition phase half-life. The terminal slope of the plasma concentration versus time curve was calculated by linear regression analysis of the log concentration versus time data. We used at least three data points to calculate the disposition half-life. Thus, in response to Dr. Ross' first question, the ritodrine concentration falls rapidly between 78 to 120 minutes because of drug distribution. The mean disposition half-life of 166 minutes is calculated after distribution is complete.

The article referenced by Dr. Ross reports a single case in which ritodrine concentration was measured after oral administration to a nonpregnant subject.[1] The cited study used radioimmunoassay to measure ritodrine and the terminal disposition half-life was determined on several plasma concentration values that were <1 ng/ml. The radioimmunoassay is unlikely to be sufficiently sensitive or specific for ritodrine to accurately measure plasma concentrations <1 ng/ml. Thus these estimates of half-life are unlikely to be correct. Further, we have shown marked differences in ritodrine kinetics between pregnant and nonpregnant human beings.[2,3] The disposition half-life in pregnancy averages 156 minutes whereas, in nonpregnant volunteers it averages 366 minutes. Finally, our calculated disposition half-life of 166 minutes is very similar to that previously determined for ritodrine after intravenous infusion.[2]

Recent Advances in Obstetrics and Gynecology, Omni Netherland Plaza Hotel, Cincinnati, Ohio, October 4-6, 1990. Sponsored by the Departments of Obstetrics and Gynecology, University of Cincinnati College of Medicine, Good Samaritan Hospital, and The Christ Hospital. For information, contact Course Coordinator, Department of Obstetrics and Gynecology, University of Cincinnati College of Medicine, 231 Bethesda Ave., Cincinnati, OH 45267-0525. Tel.: (513) 558-8440.

High Risk/Critical Care Obstetrics: Medical & Nursing Management of the 90's, Hamilton Princess Resort, Bermuda, August 11-18, 1990. For conference information contact: Jim Goodrich, CMP, Symposia Medicus, 2815 Mitchell Dr., Suite 128, Walnut Creek, CA 94598-1622. Tel.: (415) 935-7889.

NCHS to hold data users conference in August 1990. Users of data files from the National Center for Health Statistics will have a special opportunity to expand their knowledge of data resources when the National Center for Health Statistics holds its fifth biennial Data Users Conference, August 15-17, 1990, in Rockville, Maryland. The conference provides users the forum to learn of current and potential applications for the public use data sets, discuss technical and analytical issues with NCHS staff, and exchange information with other data users. A plenary session will provide a preview of future directions in data collection, analysis, and dissemination by NCHS. NCHS Director Dr. Manning Feinleib will deliver the keynote address. The 3-day conference program consists of 38 workshops on specific data files from the many NCHS data systems, as well as sessions on cross-cutting topical and analytical issues. Special sessions will be devoted to NCHS data on: health of minorities, occupational and environmental health, health and health care needs of an aging America, and HIV infection and AIDS. In addition, there will be presentations on the Center's cognitive research program to improve the quality and collection of national health statistics, on software developments, on the integrated survey design for NCHS data systems, and on new technologies in cartography and graphics. First-time conference attendees can take advantage of an overview of NCHS data systems, intended for those who are looking for more guidance about the types of data gathered by NCHS, before attending the in-depth workshops. NCHS is the federal government's primary vital and health statistics agency and is a part of the Centers for Disease Control, Public Health Service. Through interview, health examination, and health record surveys and the vital statistics system, NCHS produces a wide array of health and health-related data. More than 600 public use data files are available representing data from the more than a dozen separate data systems. There is no registration fee for the conference, but space is limited. To receive an invitation and registration packet, contact: Barbara Hetzler, NCHS, Room 1100, 6525 Belcrest Road, Hyattsville, MD. Tel.: (301) 436-7122.

Subject index*

A

Abdominal wall
Early prenatal diagnosis of gastroschisis with transvaginal ultrasonography (Guzman). 1990;162:1253-4
Successful pregnancy and normal delivery with Marlex mesh replacement of the abdominal wall (Ezra et al). 1990;162:97-8

Abnormalities
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Sonographic findings in the prenatal diagnosis of bladder exstrophy (Jaffe et al). 1990;162:675-8

Abortifacient agents; *see* RU-486

Abortion
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
Evaluation of hysteroscopic management of the septate uterus (Simpson). 1990;162:598-9 (Letter)
Prediction of residual trophoblastic tissue in first-trimester abortions and low levels of human chorionic gonadotropin β-subunit (Schiff et al). 1990;162:797-801
Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities (Check et al). 1990;162:674-5

Abortion, complications
Predictors of failed attempted abortion with the antiprogestin mifepristone (RU 486) (Grimes et al). 1990;162:910-7

Abortion, induced
Ectopic pregnancy concurrent with induced abortion: incidence and mortality (Atrash et al). 1990;162:726-30
The effects of RU-38486 on cervical ripening (Lefebvre et al). 1990;162:61-5
The efficacy of oral mifepristone (RU-38,486) with a prostaglandin E_1 analog vaginal pessary for the termination of early pregnancy: complications and patient acceptability (Hill et al). 1990;162:414-7
Fatal pulmonary embolism during legal induced abortion in the United States from 1972 to 1985 (Lawson et al). 1990;162:986-90
Intrafetal prostaglandin $F_{2\alpha}$ administration for midtrimester pregnancy termination: a case report (Christodoulou et al). 1990;162:1245-6
Orosomucoid in human pregnancy serum diminishes bioavailability of the progesterone antagonist RU 486 in rats (Steingold et al). 1990;162:523-4
Predictors of failed attempted abortion with the antiprogestin mifepristone (RU 486) (Grimes et al). 1990;162:910-7

Abortion, therapeutic
Selective termination: clinical experience and residual risks (Evans et al). 1990;162:1568-75

Abruptio placentae
Abruptio placentae after percutaneous umbilical cord sampling: a case report (Feinkind et al). 1990;162:1203-4
A prospective controlled study of outcome after trauma during pregnancy (Pearlman et al). 1990;162:1502-10

Accidents
A prospective controlled study of outcome after trauma during pregnancy (Pearlman et al). 1990;162:1502-10

Acetominophen
Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10

Acid-base equilibrium
Blood gas studies in fetal heart blood (Soothill) (Letter); (Westgren) (Reply). 1990;162:1636-7
The case for routine umbilical blood acid-base studies at delivery (Johnson et al). 1990;162:621-5 (Clin. opinion)
Changes in blood gas, acid-base parameters require adjustment (Soothill) (Letter); (Ferrazzi et al) (Reply). 1990;162:1350-1

Acidosis
The association of fetal and newborn metabolic acidosis with severe periventricular leukomalacia in the preterm newborn (Low et al). 1990;162:977-82
Effects of hypoxemia with and without acidemia on the isometric contraction time and the electromechanical delay of the fetal myocardium: an experimental study on the ovine fetus (Fouron et al). 1990;162:262-6
Severe acidosis and subsequent neurologic status (Fee et al). 1990;162:802-6

Acoustic stimulation
Caution regarding fetal acoustic stimulation in oligohydramnios (Menashe and Sherer) (Letter); (Ingemarsson and Arulkumaran) (Reply). 1990;162:603-4
Fetal acoustic stimulation in the early intrapartum period

*January, 1-302; February, 303-612; March, 613-878; April, 879-1134; May, 1135-1364; June, 1365-1736.

Acoustic stimulation—cont'd
as a predictor of subsequent fetal condition (Sarno et al). 1990;162:762-7
Adaptation, physiological
Intrauterine asphyxia and the breakdown of physiologic circulatory compensation in fetal sheep (Block et al). 1990;162:1325-31
Adenocarcinoma
Clear cell carcinoma of the sigmoid mesocolon: a tumor of the secondary müllerian system (Evans et al). 1990;162:161-3
Deoxyribonucleic acid flow cytometric analysis of cervical adenocarcinoma: prognostic significance of deoxyribonucleic acid ploidy and S-phase fraction (Leminen et al). 1990;162:848-53
Evaluation of unfavorable histologic subtypes in endometrial adenocarcinoma (Wilson et al). 1990;162:418-26
Use of serum CA 125 measurement in posttreatment surveillance of early-stage endometrial carcinoma (Patsner et al). 1990;162:427-9
Vaginal bleeding and diethylstilbestrol exposure during pregnancy: relationship to genital tract clear cell adenocarcinoma and vaginal adenosis in daughters (Sharp and Cole). 1990;162:994-1001
Adenocarcinoma, papillary
Evaluation of unfavorable histologic subtypes in endometrial adenocarcinoma (Wilson et al). 1990;162:418-26
Adhesions
Reduction of postoperative adhesions in the rat uterine horn model with poloxamer 407 (Leach and Henry). 1990;162:1317-9
Treatment-dependent and treatment-independent pregnancy among women with periadnexal adhesions (Tulandi et al). 1990;162:354-7
Uterine rupture after treatment of Asherman's syndrome (Hulka) (Letter); (Deaton et al) (Reply). 1990;162:1352-3
Adnexa uteri
Pelviscopic adnexectomy (Perry and Upchurch). 1990;162:79-81
Adnexal diseases
Treatment-dependent and treatment-independent pregnancy among women with periadnexal adhesions (Tulandi et al). 1990;162:354-7
Adnexitis
Cigarette smoking as a risk factor for pelvic inflammatory disease (Marchbanks et al). 1990;162:639-44
Interferon gamma and depressed cellular immune response (Fuith et al). 1990;162:1338 (Letter)
Adrenal cortex hormones
Corticosteroid treatment of pregnant women with antiphospholipid antibodies and previous fetal loss (Lubbe and Pattison) (Letter); (Lockshin and Druzin) (Reply). 1990;162:1341-3
Perinatal factors associated with the respiratory distress syndrome (Bryan et al). 1990;162:476-81
Adrenal gland hyperfunction
Cushing's syndrome and pregnancy (Aron et al). 1990;162:244-52 (Curr. dev.)
Spontaneous resolution of Cushing's syndrome after pregnancy (Aron et al). 1990;162:472-4
Adrenal hyperplasia, congenital
Pseudogene/functional gene ratio in late-onset 21-hydroxylase-deficient adrenal hyperplasia (Azziz et al). 1990;162:633-8
Adrenergic beta receptor agonists
The influence of drugs with β-adrenergic actions on prostacyclin production of human umbilical cord vessels (Lippert et al). 1990;162:288-90 (Letter)
Adrenergic beta receptor blockaders
The influence of drugs with β-adrenergic actions on prostacyclin production of human umbilical cord vessels (Lippert et al). 1990;162:288-90 (Letter)
Adrenergic receptors; *see* Receptors, adrenergic
Adrenergic receptors, alpha; *see* Receptors, adrenergic, alpha
Aerobic exercise; *see* Exercise
Aging
The effect of aging on hypothalamic function in oophorectomized women (Alexander et al). 1990;162:446-9
Alcohol, ethyl
Functional tolerance to the effects of ethanol on fetal biophysical activities? (Smith et al) (Letter); (Castillo and Devoe) (Reply). 1990;162:1631-2
Allergens
Recurrent allergic vulvovaginitis: treatment with *Candida albicans* allergen immunotherapy (Rigg et al). 1990;162:332-6
Allergy; *see* Hypersensitivity
Alpha 1-antitrypsin
Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9
Alpha fetoproteins
Maternal serum α-fetoprotein in twin pregnancy (Johnson et al). 1990;162:1020-5
Maternal serum α-fetoprotein levels in pregnancies among black and white women with fetal open spina bifida: a United States Collaborative Study (Johnson et al). 1990;162:328-31
Maternal serum α-fetoprotein screening for fetal Down syndrome in the United States: results of a survey (Palomaki et al). 1990;162:317-21
Amenorrhea
Uterine rupture after treatment of Asherman's syndrome (Hulka) (Letter); (Deaton et al) (Reply). 1990;162:1352-3
The American Board of Obstetrics and Gynecology
New certifications: subspecialty of Basic. 1990;162:1645-61
New certifications: subspecialty of Gynecologic Oncology. 1990;162:1663
New certifications: subspecialty of Maternal-Fetal Medicine. 1990;162:1662-3
New certifications: subspecialty of Reproductive Endocrinology. 1990;162:1661-2
Recertifications: subspecialty of Basic. 1990;162:1663-8
American Gynecological and Obstetrical Society
Transactions of the eighth annual meeting of the American Gynecological and Obstetrical Society. 1990;162:879-982
American Journal of Obstetrics and Gynecology
Journal article appraisal (Capecchi). 1990;162:1121 (Letter)
Summary of analysis of published articles. 1990;162:613-4 (Editorial)
Amino acids
The neuropeptide histidyl proline diketopiperazine throughout human pregnancy: an inverse correlation with amniotic fluid prolactin (Wolf et al). 1990;162:740-5
Umbilical amino acid concentrations in normal and growth-

retarded fetuses sampled in utero by cordocentesis (Cetin et al). 1990;162:253-61

Ammonium chloride

Ammonium chloride pretreatment of bloody amniotic fluids for cytogenetic analysis (Macera et al). 1990;162:868-70 (Letter)

Amniocentesis

An analysis of antenatal tests to detect infection in preterm premature rupture of the membranes (Ohlsson and Wang). 1990;162:809-18 (Curr. dev.)

Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6

Significance of observing no fluid at amniotomy (Druzin and Adams). 1990;162:1006-7

Ultrasonography-guided early amniocentesis in singleton pregnancies (Hanson et al). 1990;162:1376-83

Amnioinfusion; *see* Amniotic fluid

Amnion

Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9

CA 125 is released by human amnion cells in culture (Barbati et al). 1990;162:266-8

Different characteristics of amniotic and cervical collagenous tissue during pregnancy and delivery: a morphologic study (Yoshida and Manabe). 1990;162:190-3

Immunocytochemical localization and messenger ribonucleic acid concentrations for human placental lactogen in amnion, chorion, decidua, and placenta (Sakbun et al). 1990;162:1310-7

Mechanisms of parturition: the transfer of prostaglandin E_2 and 5-hydroxyeicosatetraenoic acid across fetal membranes (Bennett et al). 1990;162:683-7

Production of prostaglandin E_2 by human amnion in vitro in response to addition of media conditioned by microorganisms associated with chorioamnionitis and preterm labor (Lamont et al). 1990;162:819-25

Amniotic fluid

Ammonium chloride pretreatment of bloody amniotic fluids for cytogenetic analysis (Macera et al). 1990;162:868-70 (Letter)

Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9

The amniotic fluid index in normal human pregnancy (Moore and Cayle). 1990;162:1168-73

Amniotic fluid volume increase after amnioinfusion of a fixed volume (Strong et al). 1990;162:746-8

Caution regarding fetal acoustic stimulation in oligohydramnios (Menashe and Sherer) (Letter); (Ingemarsson and Arulkumaran) (Reply). 1990;162:603-4

Detection of platelet-activating factor in amniotic fluid of complicated pregnancies (Hoffman et al). 1990;162:525-8

The ferning test for detection of amniotic fluid contamination in umbilical blood samples (Chao et al). 1990;162:1207-13

Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention (Crombleholme et al). 1990;162:1239-44

Immunoreactive corticotropin-releasing hormone in amniotic fluid (Sasaki et al). 1990;162:194-8

Intrafetal prostaglandin $F_{2\alpha}$ administration for midtrimester pregnancy termination: a case report (Christodoulou et al). 1990;162:1245-6

Maternal indomethacin therapy in the treatment of polyhydramnios (Mamopoulos et al). 1990;162:1225-9

Neonatal outcome after prolonged preterm rupture of the membranes (Rotschild et al). 1990;162:46-52

The neuropeptide histidyl proline diketopiperazine throughout human pregnancy: an inverse correlation with amniotic fluid prolactin (Wolf et al). 1990;162:740-5

Oligohydramnios in each sac of a triplet gestation caused by Motrin—fulfilling Kock's postulates (Wiggins and Elliott). 1990;162:460-1

Oligohydramnios sequence and renal tubular malformation associated with maternal enalapril use (Cunniff et al). 1990;162:187-9

Prophylactic intrapartum amnioinfusion: a randomized clinical trial (Strong et al). 1990;162:1370-5

A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9

Serum fructosamine and amniotic fluid insulin levels in patients with gestational diabetes and healthy control subjects (Hofmann et al). 1990;162:1174-7

Significance of observing no fluid at amniotomy (Druzin and Adams). 1990;162:1006-7

The tap test: confirmation of a simple, rapid, inexpensive, and reliable indicator of fetal pulmonary maturity (Socol). 1990;162:218-22

Transient oligohydramnios in a severely hypovolemic gravid woman at 35 weeks' gestation, with fluid reaccumulating immediately after intravenous maternal hydration (Sherer et al). 1990;162:770-1

Treatment of twins with hydramnios (Thorp and Chescheir) (Letter); (Lange and Harman) (Reply). 1990;162:1625

Amniotic fluid, animal

Immunoreactive corticotropin-releasing hormone in amniotic fluid (Sasaki et al). 1990;162:194-8

Ampicillin

Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9

Analgesia, epidural

Epidural analgesia and autonomic hyperreflexia: a case report (Katz et al). 1990;162:471-2

Analgesics

Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10

Anaphylaxis

Anaphylaxis and cefotetan (Faro and Martens). 1990;162:296 (Letter)

Warnings in use of cefotetan (Pocelinko) (Letter); (Bloomberg) (Reply). 1990;162:296-7

Androgens

The antiestrogenic effect of cigarette smoking in women (Baron et al). 1990;162:502-14 (Curr. dev.)

Insulin-dependent diabetes mellitus associated with danazol (Seifer et al). 1990;162:474-5

Anemia

Blood sampling and transfusion in utero suggested in the pumping twin (Jakobi and Zimmer) (Letter); (Stiller and Romero) (Reply). 1990;162:1632-3

Chronic, massive fetomaternal hemorrhage treated with repeated fetal intravascular transfusions (Fischer et al). 1990;162:203-4

Doppler examination of the middle cerebral artery in anemic fetuses (Vyas et al). 1990;162:1066-8

Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe

Anemia—cont'd
red blood cell alloimmunization (Mari et al). 1990;162:1060-4
Need for plasma volume estimation (Goodlin). 1990;162:601 (Letter)
Prediction of fetal anemia by measurement of the mean blood velocity in the fetal aorta (Nicolaides et al). 1990;162:209-12
Anencephaly
First-trimester diagnosis of exencephaly (Kennedy et al). 1990;162:461-3
Anesthetics, local
Pregnancy does not alter lidocaine toxicity (Morishima et al). 1990;162:1320-4
Aneuploidy
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Deoxyribonucleic acid flow cytometric analysis of cervical adenocarcinoma: prognostic significance of deoxyribonucleic acid ploidy and S-phase fraction (Leminen et al). 1990;162:848-53
Angiography
Angiographic embolization (Heffner) (Letter); (Chin) (Reply). 1990;162:1345-6
Angiokeratoma corporis diffusum
Demonstration of Fabry's disease deposits in placenta (Popli et al). 1990;162:464-5
Angiotensin-converting enzyme inhibitors
Oligohydramnios sequence and renal tubular malformation associated with maternal enalapril use (Cunniff et al). 1990;162:187-9
Angiotensin II
Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7
Announcements
Changes in gynecologic cancer staging by the International Federation of Gynecology and Obstetrics. 1990;162:610-1
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7
Anoxemia
Antepartum heart rate patterns in small-for-gestational-age third-trimester fetuses: correlations with blood gas values obtained at cordocentesis (Visser et al). 1990;162:698-703
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al). 1990;162:382-6
Anoxemia, animal
Effects of hypoxemia with and without acidemia on the isometric contraction time and the electromechanical delay of the fetal myocardium: an experimental study on the ovine fetus (Fouron et al). 1990;162:262-6
Nuchal muscle activity at different levels of hypoxemia in fetal sheep (Woudstra et al). 1990;162:559-64
Anti-antibodies; *see* **Antibodies, anti-idiotypic**
Antibiotics
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43
Is obstetric progress dependent on rigorous randomized controlled trials? (Goodlin) (Letter); (Ohlsson) (Reply). 1990;162:1353-5
Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes (Novy et al). 1990;162:1412-20
Single-dose antibiotic prophylaxis for patients undergoing extended pelvic surgery for gynecologic malignancy (Orr et al). 1990;162:718-21
Antibodies
A longitudinal study of maternal digoxin-like immunoreactive substances in normotensive pregnancy and pregnancy-induced hypertension (Kerkez et al). 1990;162:783-7
Pathophysiology of antiphospholipid antibodies: absence of prostaglandin-mediated effects on cultured endothelium (Dudley et al). 1990;162:953-9
Antibodies, anti-idiotypic
Anti-vascular endothelial cell antibodies in severe preeclampsia (Rappaport et al). 1990;162:138-46
Corticosteroid treatment of pregnant women with antiphospholipid antibodies and previous fetal loss (Lubbe and Pattison) (Letter); (Lockshin and Druzin) (Reply). 1990;162:1341-3
Natural immunoglobulin M antibodies against *Toxoplasma gondii* during pregnancy (Gussetti et al) (Letter); (Konishi) (Reply). 1990;162:1359-60
Antibodies, monoclonal
Heterogeneity of antigen expression in advanced epithelial ovarian cancer (Berchuck et al). 1990;162:883-8
Antibody formation
Immunohistologic evidence that villitis in human normal term placentas is an immunologic lesion (Labarrere et al). 1990;162:515-22
Anticoagulants
Measured menstrual blood loss in women with a bleeding disorder or using oral anticoagulant therapy (van Eijkeren et al). 1990;162:1261-3
Anticonvulsants
Magnesium sulfate is the ideal anticonvulsant in preeclampsia-eclampsia (Sibai). 1990;162:1141-5 (Clin. opinion)
Antigen-antibody reactions
Anti-vascular endothelial cell antibodies in severe preeclampsia (Rappaport et al). 1990;162:138-46
Antigens, tumor-associated
Predictive value and prevalence (Kürzl) (Letter); (Patsner) (Reply). 1990;162:871-2
Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities (Check et al). 1990;162:674-5
Antigens, tumor-associated, carbohydrate
CA 125 levels analyzed (Fuith) (Letter); (Sagawa et al) (Reply). 1990;162:1358-9
CA 125 in peritoneal fluid (Williams) (Letter); (Dawood et al) (Reply). 1990;162:296
CA 125 is released by human amnion cells in culture (Barbati et al). 1990;162:266-8
Heterogeneity of antigen expression in advanced epithelial ovarian cancer (Berchuck et al). 1990;162:883-8
Use of serum CA 125 measurement in posttreatment surveillance of early-stage endometrial carcinoma (Patsner et al). 1990;162:427-9
Antimicrobial prophylaxis; *see* **Antibiotics**
Antineoplastic agents
Gestational trophoblastic disease: What have we learned in the past decade? (Jones). 1990;162:1286-95

A 62-year-old woman with endodermal sinus tumor of the ovary (Kinoshita). 1990;162:760-2

Antiphospholipid antibodies; *see* Phospholipids

Aorta

Prediction of fetal anemia by measurement of the mean blood velocity in the fetal aorta (Nicolaides et al). 1990;162:209-12

Aortic valve stenosis

Prenatal diagnosis of valvar aortic stenosis by Doppler echocardiography and magnetic resonance imaging (Hata et al). 1990;162:1068-70

Apgar score

Predicting neonatal morbidity after perinatal asphyxia: a scoring system (Portman et al). 1990;162:174-82

Apoptosis; *see* Cell fractionation

ARDS; *see* Respiratory distress syndrome, adult

Arginine

Fetal hemodynamic and fetoplacental vascular response to exogenous arginine vasopressin (Irion et al). 1990;162:1115-20

Arnold-Chiari deformity

Evaluation of the lemon and banana signs in one hundred thirty fetuses with open spina bifida (Van den Hof et al). 1990;162:322-7

Aromatase

In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14

Arterial flow velocity; *see* Blood flow velocity

Asphyxia neonatorum

The case for routine umbilical blood acid-base studies at delivery (Johnson et al). 1990;162:621-5 (Clin. opinion)

Doppler measurements of fetal and uteroplacental circulations: relationship with umbilical venous blood gases measured at cordocentesis (Bilardo et al). 1990;162:115-20

Intrapartum asphyxia in the preterm fetus <2000 gm (Low et al). 1990;162:378-82

Intrapartum fetal asphyxia (Barton et al) (Letter); (Low) (Reply). 1990;162:1123-4

Predicting neonatal morbidity after perinatal asphyxia: a scoring system (Portman et al). 1990;162:174-82

Severe acidosis and subsequent neurologic status (Fee et al). 1990;162:802-6

What is fetal distress? (Parer and Livingston). 1990;162:1421-7

Asphyxia neonatorum, animal

Intrauterine asphyxia and the breakdown of physiologic circulatory compensation in fetal sheep (Block et al). 1990;162:1325-31

Aspirin

Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10

Atrial natriuretic factor; *see* Natriuretic peptides, atrial

Auditory perception

Sound environment of the fetal sheep (Gerhardt et al). 1990;162:282-7

Autoimmune diseases

Hormone activity and autoimmune function (Pun and Ho) (Letter); (Gleicher and El-Roeiy) (Reply). 1990;162:866-7

Induction of class II major histocompatibility complex antigen expression in human granulosa cells by interferon gamma: a potential mechanism contributing to autoimmune ovarian failure (Hill et al). 1990;162:534-40

Autonomic nervous system diseases

Epidural analgesia and autonomic hyperreflexia: a case report (Katz et al). 1990;162:471-2

Autotransfusion; *see* Blood transfusion, autologous

B

B-lymphocytes

Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14

Bacteriuria

Bacteriuria in the puerperium (Stray-Pedersen et al). 1990;162:792-7

Ballentyne syndrome; *see* Hydrops fetalis

Beta adrenergic receptor blockaders; *see* Adrenergic beta receptor blockaders

Biological availability

Orosomucoid in human pregnancy serum diminishes bioavailability of the progesterone antagonist RU 486 in rats (Steingold et al). 1990;162:523-4

Biological products

Mechanical performance of square knots and sliding knots in surgery: a comparative study (van Rijssel et al). 1990;162:93-7

Biological transport

The relationship of maternal erythrocyte oxygen transport parameters to intrauterine growth retardation (Brown et al). 1990;162:223-9

Biophysical profile; *see* Fetal monitoring

Biopsy

Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92

Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—preliminary data (Raman et al). 1990;162:1511-7

Breast cancer detection: experience in a suburban community (Goodno). 1990;162:1393-7

The impact of luteal phase inadequacy in an infertile population (Wentz et al). 1990;162:937-45

Mitochondrial myopathy and preeclampsia associated with pregnancy (Berkowitz et al). 1990;162:146-7

Surgical management of breast disease in an obstetrics and gynecology group (Hall et al). 1990;162:1526-34

Survival and cell acquisition rates after preimplantation embryo biopsy: use of two mechanical techniques and two mouse strains (Roudebush et al). 1990;162:1084-90

Treatment of cervical intraepithelial neoplasia: experience with the low-voltage diathermy loop (Whiteley and Oláh). 1990;162:1272-7

Birth injuries

Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries (Robertson et al). 1990;162:1436-44

Birth weight

Birth weight discordancy in male-first and female-first pairs of unlike-sexed twins (Blickstein and Weissman). 1990;162:661-3

Calculation of fetoplacental volume (Moise). 1990;162:596 (Letter)

Effects of birth weight and sociodemographic variables on

Birth weight—cont'd
mental development of neonatal intensive care unit survivors (Resnick et al). 1990;162:374-8
Fetal weight error perpetuated (DuBose). 1990;162:876 (Letter)
Intrauterine growth and spastic cerebral palsy. I. Association with birth weight for gestational age (Blair and Stanley). 1990;162:229-37
Macrosomia: influence of maternal overweight among a low-income population (Larsen et al). 1990;162:490-4
Mathematic form corrected (Habekovic) (Letter); (Sabbagha) (Reply). 1990;162:1351
Ultrasonographic estimation of fetal weight in the clinically macrosomic fetus (Hirata et al). 1990;162:238-42
Bladder exstrophy
Sonographic findings in the prenatal diagnosis of bladder exstrophy (Jaffe et al). 1990;162:675-8
Blastocyst, animal
Survival and cell acquisition rates after preimplantation embryo biopsy: use of two mechanical techniques and two mouse strains (Roudebush et al). 1990;162:1084-90
Blastomeres, animal
Survival and cell acquisition rates after preimplantation embryo biopsy: use of two mechanical techniques and two mouse strains (Roudebush et al). 1990;162:1084-90
Bleeding disorders; *see* Hematologic diseases
Blindness
Postpartum pulmonary embolus as an unusual cause of cortical blindness (Stiller et al). 1990;162:696-7
Blood circulation
Doppler examination of the middle cerebral artery in anemic fetuses (Vyas et al). 1990;162:1066-8
Doppler measurements of fetal and uteroplacental circulations: relationship with umbilical venous blood gases measured at cordocentesis (Bilardo et al). 1990;162:115-20
Blood circulation, animal
Intrauterine asphyxia and the breakdown of physiologic circulatory compensation in fetal sheep (Block et al). 1990;162:1325-31
Blood coagulation
Changes in hemostasis activity during delivery and the immediate postpartum period (Gerbasi et al). 1990;162:1158-63
Immunohistologic evidence that villitis in human normal term placentas is an immunologic lesion (Labarrere et al). 1990;162:515-22
Blood coagulation factors
Postpartum Budd-Chiari syndrome with prolonged hypercoagulability state (Ilan et al). 1990;162:1164-5
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Blood flow velocity
Changes in blood gas, acid-base parameters require adjustment (Soothill) (Letter); (Ferrazzi et al) (Reply). 1990;162:1350-1
Changes in uterine blood flow during human pregnancy (Thaler et al). 1990;162:121-5
The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: a prospective blinded study (Maulik et al). 1990;162:1518-25
Direct determination of the ovine fetal umbilical artery blood flow waveform (Irion and Clark). 1990;162:541-9
Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7
Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4
Local cerebral blood flow is increased in rapid-eye-movement sleep in fetal sheep (Abrams et al). 1990;162:278-81
Prediction of fetal anemia by measurement of the mean blood velocity in the fetal aorta (Nicolaides et al). 1990;162:209-12
The value of Doppler assessment of the uteroplacental circulation in predicting preeclampsia or intrauterine growth retardation (Jacobson et al). 1990;162:110-4
Blood gas analysis
Antepartum heart rate patterns in small-for-gestational-age third-trimester fetuses: correlations with blood gas values obtained at cordocentesis (Visser et al). 1990;162:698-703
Blood gas studies in fetal heart blood (Soothill) (Letter); (Westgren) (Reply). 1990;162:1636-7
Changes in blood gas, acid-base parameters require adjustment (Soothill) (Letter); (Ferrazzi et al) (Reply). 1990;162:1350-1
Doppler measurements of fetal and uteroplacental circulations: relationship with umbilical venous blood gases measured at cordocentesis (Bilardo et al). 1990;162:115-20
Fetal umbilical blood gas values as diagnostic criteria (Weiner) (Letter); (Warren et al) (Reply). 1990;162:1124-5
Relation of rate of urine production to oxygen tension in small-for-gestational-age fetuses (Nicolaides et al). 1990;162:387-91
The relationship between the umbilical artery systolic/diastolic ratio and umbilical blood gas measurements in specimens obtained by cordocentesis (Weiner). 1990;162:1198-202
Blood gas monitoring, transcutaneous
Nuchal muscle activity at different levels of hypoxemia in fetal sheep (Woudstra et al). 1990;162:559-64
Blood platelets
The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
Blood pressure
The relationship between experimentally determined litter size and maternal blood pressure in spontaneously hypertensive rats (Ahokas and Sibai). 1990;162:841-7
Blood pressure, high; *see* Hypertension
Blood transfusion
Chronic, massive fetomaternal hemorrhage treated with repeated fetal intravascular transfusions (Fischer et al). 1990;162:203-4
Blood transfusion, autologous
Sacrospinous ligament fixation (Cabrera and Szekely). 1990;162:295-6 (Letter)
Blood transfusion, intrauterine
Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4

Intrauterine transfusion—intraperitoneal versus intravascular approach: a case-control comparison (Harman et al). 1990;162:1053-9

Blood volume
Calculation of fetoplacental volume (Moise). 1990;162:596 (Letter)

Body weight
Prepregnancy weight status, prenatal weight gain, and the outcome of term twin gestations (Brown and Schloesser). 1990;162:182-6

Bone loss, perimenopausal; *see* Osteoporosis

Books
Books received. 1990;162:301, 1669

Brachytherapy
Interstitial radiotherapy for the treatment of advanced or recurrent vulvar and distal vaginal malignancy (Hoffman et al). 1990;162:1278-82

Brain, blood supply, animal
Local cerebral blood flow is increased in rapid-eye-movement sleep in fetal sheep (Abrams et al). 1990;162:278-81

Brain damage, chronic
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
The association of fetal and newborn metabolic acidosis with severe periventricular leukomalacia in the preterm newborn (Low et al). 1990;162:977-82

Breast cancer; *see* Breast neoplasms

Breast diseases
Surgical management of breast disease in an obstetrics and gynecology group (Hall et al). 1990;162:1526-34

Breast neoplasms
The antiestrogenic effect of cigarette smoking in women (Baron et al). 1990;162:502-14 (Curr. dev.)
Breast cancer detection: experience in a suburban community (Goodno). 1990;162:1393-7
Subspecialty of gynecologic oncology proposed to manage breast disease (Kelley). 1990;162:1638 (Letter)
Surgical management of breast disease in an obstetrics and gynecology group (Hall et al). 1990;162:1526-34

Breech presentation
The efficacy of external cephalic version and its impact on the breech experience (Hanss). 1990;162:1459-64
Ultrasonography and external cephalic version at term (Donald and Barton). 1990;162:1542-7

Bromocriptine
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162:1065-6

Budd-Chiari syndrome; *see* Hepatic vein thrombosis

Bupivacaine
Pregnancy does not alter lidocaine toxicity (Morishima et al). 1990;162:1320-4

Buserelin acetate
Gonadotropin-releasing hormone analogs in the treatment of endometriomas (Schenken). 1990;162:579-81 (Symposium)

C

CA-125; *see* Antigens, tumor-associated

Calcium
Effects of nafarelin versus danazol on lipids and calcium metabolism (Bergquist). 1990;162:589-91 (Symposium)
Effects of relaxin on calcium concentrations (Young) (Letter); (Goldsmith) (Reply). 1990;162:605

Calcium channels
Some electrical properties of human pregnant myometrium (Inoue et al). 1990;162:1090-8

Cancer metastasis; *see* Neoplasm metastasis

Cancer staging; *see* Neoplasm staging

Candida albicans
Recurrent allergic vulvovaginitis: treatment with *Candida albicans* allergen immunotherapy (Rigg et al). 1990;162:332-6

Candidiasis, vulvovaginal
Recurrent allergic vulvovaginitis: treatment with *Candida albicans* allergen immunotherapy (Rigg et al). 1990;162:332-6

Captopril
Oligohydramnios sequence and renal tubular malformation associated with maternal enalapril use (Gunniff et al). 1990;162:187-9

Carbohydrates
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)

Carcinoma
Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—preliminary data (Raman et al). 1990;162:1511-7
Clear cell carcinoma of the sigmoid mesocolon: a tumor of the secondary müllerian system (Evans et al). 1990;162:161-3
Flow cytometric evaluation of epithelial ovarian cancer (Barnabei et al). 1990;162:1584-92

Carcinoma, squamous cell
Lichen sclerosus, invasive squamous cell carcinoma, and human papillomavirus (Neill et al). 1990;162:1633-4 (Letter)
Stage IA_2 squamous carcinoma of the cervix: difficult diagnosis and therapeutic dilemma (Greer et al). 1990;162:1406-11

Carcinoma in situ
The mons pubis: an excellent graft donor site in gynecologic surgery (Dudzinski and Rader). 1990;162:722-5

Cardiopulmonary arrest; *see* Heart arrest

Cardiotocography
Patient-recorded domiciliary fetal monitoring (Lindsay et al). 1990;162:466-70

Cardiovascular collapse; *see* Heart arrest

Cardiovascular diseases
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)

Cardiovascular system
Cardiovascular response to maximal cycle exercise during pregnancy and at two and seven months post partum (Sady et al). 1990;162:1181-5

Cardiovascular system, animal
Pregnancy increases cardiovascular toxicity to cocaine (Woods and Plessinger). 1990;162:529-33
Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10

Catecholamines
Characterization of norepinephrine sensitivity in the maternal splanchnic circulation during pregnancy (Crandall et al). 1990;162:1296-301

Catheterization, Swan-Ganz
Pulmonary artery catheterization in severe preeclampsia (Goodlin) (Letter); (Clark and Cotton) (Reply). 1990;162:601-3

Cefazolin
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Cefonicid
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Cefotetan
Anaphylaxis and cefotetan (Faro and Martens). 1990;162:296 (Letter)
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Warnings in use of cefotetan (Pocelinko) (Letter); (Bloomberg) (Reply). 1990;162:296-7
Cefoxitin
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Ceftizoxime
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Cell death; *see* Cell survival
Cell fractionation
Spontaneous cell death in the chorion laeve (Parmley). 1990;162:1576-83
Cell survival
Spontaneous cell death in the chorion laeve (Parmley). 1990;162:1576-83
Survival and cell acquisition rates after preimplantation embryo biopsy: use of two mechanical techniques and two mouse strains (Roudebush et al). 1990;162:1084-90
Cells, cultured
CA 125 is released by human amnion cells in culture (Barbati et al). 1990;162:266-8
In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14
Cellular immune response; *see* Immunity, cellular
Central Association of Obstetricians and Gynecologists
Transactions of the fifty-seventh annual meeting of the Central Association of Obstetricians and Gynecologists. 1990;162:1499-624
Central venous pressure
Reliance on central venous pressure with regard to fluid management in preeclampsia deemed dangerous (Clark). 1990;162:598 (Letter)
Cerebellar ataxia
Maternal reproductive histories in ataxic cerebral palsy (Miller). 1990;162:242-3
Cerebral aneurysm
Aneurysm of the vein of Galen: a new cause for Ballantyne syndrome (Ordorica et al). 1990;162:1166-7
Cerebral arteries
Doppler examination of the middle cerebral artery in anemic fetuses (Vyas et al). 1990;162:1066-8
Middle cerebral artery blood flow in normal and growth-retarded fetuses (Veille and Cohen). 1990;162:391-6
Cerebral blood flow, animal; *see* Cerebrovascular circulation, animal
Cerebral hemorrhage
The association of fetal and newborn metabolic acidosis with severe periventricular leukomalacia in the preterm newborn (Low et al). 1990;162:977-82
Prenatal diagnosis of intracerebellar hemorrhage: case report (Jennett et al). 1990;162:1472-5
Cerebral palsy
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
Intrauterine growth and spastic cerebral palsy. I. Association with birth weight for gestational age (Blair and Stanley). 1990;162:229-37
Maternal reproductive histories in ataxic cerebral palsy (Miller). 1990;162:242-3
The placenta in the litigation process (Benirschke). 1990;162:1445-50
Cerebral veins
Aneurysm of the vein of Galen: a new cause for Ballantyne syndrome (Ordorica et al). 1990;162:1166-7
Cerebrovascular circulation, animal
Local cerebral blood flow is increased in rapid-eye-movement sleep in fetal sheep (Abrams et al). 1990;162:278-81
Cervical cerclage; *see* Cervix incompetence
Cervical intraepithelial neoplasia; *see* Cervix dysplasia
Cervical pregnancy; *see* Pregnancy, ectopic
Cervical stenosis; *see* Cervix uteri, pathology
Cervix diseases
Clindamycin therapy for *Chlamydia trachomatis* in women (Campbell and Dodson). 1990;162:343-7
Effect of the menstrual cycle on detection and typing of human papillomavirus in uterine cervical cells (McNicol et al). 1990;162:1037-41
Treatment of cervical intraepithelial neoplasia: experience with the low-voltage diathermy loop (Whiteley and Oláh). 1990;162:1272-7
Cervix dysplasia
Causal effect questioned (Amstey) (Letter); (Carson) (Reply). 1990;162:868
Effect of the menstrual cycle on detection and typing of human papillomavirus in uterine cervical cells (McNicol et al). 1990;162:1037-41
Studies on cervical intraepithelial neoplasia: the level of octadeca-9,11-dienoic acid and measurement of free radical content by electron spin resonance spectroscopy (Wickens et al). 1990;162:854-8
Temporal associations of human papillomavirus infection with cervical cytologic abnormalities (Lorincz et al). 1990;162:645-51
Treatment of cervical intraepithelial neoplasia: experience with the low-voltage diathermy loop (Whiteley and Oláh). 1990;162:1272-7
Cervix incompetence
Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance (Lorenz et al). 1990;162:1603-10
Results of ultrasonography not in agreement (Weinraub et al). 1990;162:596-7 (Letter)
Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes (Novy et al). 1990;162:1412-20
Cervix mucus
The validity of the postcoital test (Griffith and Grimes). 1990;162:615-20 (Clin. opinion)
Cervix neoplasms
Causal effect questioned (Amstey) (Letter); (Carson) (Reply). 1990;162:868
Deoxyribonucleic acid flow cytometric analysis of cervical adenocarcinoma: prognostic significance of deoxyribonucleic acid ploidy and S-phase fraction (Leminen et al). 1990;162:848-53

Predictive value and prevalence (Kürzl) (Letter); (Patsner) (Reply). 1990;162:871-2
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Primary cervical melanoma (Divers) (Letter); (Sloan) (Reply). 1990;162:293
Stage IA_2 squamous carcinoma of the cervix: difficult diagnosis and therapeutic dilemma (Greer et al). 1990;162:1406-11
Studies on cervical intraepithelial neoplasia: the level of octadeca-9,11-dienoic acid and measurement of free radical content by electron spin resonance spectroscopy (Wickens et al). 1990;162:854-8
Temporal associations of human papillomavirus infection with cervical cytologic abnormalities (Lorincz et al). 1990;162:645-51

Cervix uteri
Cervical length may change during ultrasonographic examination (Sonek et al). 1990;162:1355-7 (Letter)
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
Different characteristics of amniotic and cervical collagenous tissue during pregnancy and delivery: a morphologic study (Yoshida and Manabe). 1990;162:190-3
The effects of RU-38486 on cervical ripening (Lefebvre et al). 1990;162:61-5
Myometrial activity after local application of prostaglandin E_2 for cervical ripening and term labor induction (Granström et al). 1990;162:691-4
Vaginal ultrasonographic assessment of cervical length changes during normal pregnancy (Kushnir et al). 1990;162:991-3

Cervix uteri, cytology
Genetic screening with exfoliated cervicovaginal cells collected by a noninvasive lavage technique performed during routine gynecologic cancer screening (Burk and Spitzer). 1990;162:652-4
Temporal associations of human papillomavirus infection with cervical cytologic abnormalities (Lorincz et al). 1990;162:645-51

Cervix uteri, pathology
Pneumatometra (Muram et al). 1990;162:1282-3

Cesarean section
Cesarean salpingectomy rare but not first (Pelosi). 1990;162:605-6 (Letter)
A comparison of the morbidity of midforceps and cesarean delivery (Bashore et al). 1990;162:1428-35
The Green Bay cesarean section study. I. The physician factor as a determinant of cesarean birth rates (DeMott and Sandmire). 1990;162:1593-602
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43
Low segment cesarean section: a supracervical hysterotomy (Reamy). 1990;162:866 (Letter)
A new method for gaining entry into the scarred anterior cul-de-sac during transvaginal hysterectomy (Hoffman and Jaeger). 1990;162:1269-70
Physician characteristics and cesarean delivery (Barton) (Letter); (Berkowitz) (Reply). 1990;162:1641-2
Sacrospinous ligament fixation (Cabrera and Szekely). 1990;162:295-6 (Letter)
Vaginal birth after cesarean or repeat cesarean section: Medical risks or social realities? (Kirk et al). 1990;162:1398-405
The Zavanelli maneuver (Dimitry). 1990;162:1343 (Letter)

Chemotherapy; *see* Antineoplastic agents

Child development
Effects of birth weight and sociodemographic variables on mental development of neonatal intensive care unit survivors (Resnick et al). 1990;162:374-8

***Chlamydia* infections**
Oral contraceptives and infection rates (Grimes and Mishell) (Letter); (Louv et al) (Reply). 1990;162:1121-2

Chlamydia trachomatis
Chlamydia trachomatis infection in pregnancy and effect of treatment on outcome (Ryan et al). 1990;162:34-9
Clindamycin therapy for *Chlamydia trachomatis* in women (Campbell and Dodson). 1990;162:343-7
Does previous *Chlamydia trachomatis* infection influence the pregnancy rate of in vitro fertilization and embryo replacement (Osser et al). 1990;162:40-4

Chorioamnionitis
An analysis of antenatal tests to detect infection in preterm premature rupture of the membranes (Ohlsson and Wang). 1990;162:809-18 (Curr. dev.)
Production of prostaglandin E_2 by human amnion in vitro in response to addition of media conditioned by microorganisms associated with chorioamnionitis and preterm labor (Lamont et al). 1990;162:819-25
Spontaneous cell death in the chorion laeve (Parmley). 1990;162:1576-83

Chorion
Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9
Immunocytochemical localization and messenger ribonucleic acid concentrations for human placental lactogen in amnion, chorion, decidua, and placenta (Sakbun et al). 1990;162:1310-7
Mechanisms of parturition: the transfer of prostaglandin E_2 and 5-hydroxyeicosatetraenoic acid across fetal membranes (Bennett et al). 1990;162:683-7
Spontaneous cell death in the chorion laeve (Parmley). 1990;162:1576-83

Chorionic gonadotropins; *see* Gonadotropins, chorionic

Chorionic villi
Immunohistologic evidence that villitis in human normal term placentas is an immunologic lesion (Labarrere et al). 1990;162:515-22

Chorionic villi sampling
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Cytogenetic results of chorionic villus sampling: high success rate and diagnostic accuracy in the United States collaborative study (Ledbetter et al). 1990;162:495-501 (Curr. invest.)
Embryoscopy: description and utility of a new technique (Cullen et al). 1990;162:82-6
Feasibility of placental biopsy in the second trimester for fetal diagnosis (Saura et al) (Letter); (Chieri) (Reply). 1990;162:1362-3
Fetomaternal transfusion depends on amount of chorionic villi aspirated but not on method of chorionic villus sampling (Shulman et al). 1990;162:1185-8

Choroid plexus, abnormalities
Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6
Chromosome abnormalities
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Cordocentesis for rapid karyotyping (Shah et al). 1990;162:1548-53
Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52
Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities (Check et al). 1990;162:674-5
Cigarette smoking; *see* **Smoking**
Cisplatin
Gestational trophoblastic disease: What have we learned in the past decade? (Jones). 1990;162:1286-95
Citrovorum factor
Reproductive performance after methotrexate treatment of ectopic pregnancy (Stovall et al). 1990;162:1620-4
Clear cell carcinoma; *see* **Adenocarcinoma**
Clindamycin
Clindamycin therapy for *Chlamydia trachomatis* in women (Campbell and Dodson). 1990;162:343-7
Clinical opinion
Clinical opinion. 1990;162:1-9, 303-16, 615-32, 983-5, 1135-45
Clinical trials
Is obstetric progress dependent on rigorous randomized controlled trials? (Goodlin) (Letter); (Ohlsson) (Reply). 1990;162:1353-5
Coagulation, blood; *see* **Blood coagulation**
Cocaine
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162:1065-6
Pregnancy increases cardiovascular toxicity to cocaine (Woods and Plessinger). 1990;162:529-33
The prevalence of substance abuse in patients with suspected preterm labor (Ney et al). 1990;162:1562-7
Collagen
Different characteristics of amniotic and cervical collagenous tissue during pregnancy and delivery: a morphologic study (Yoshida and Manabe). 1990;162:190-3
Colposcopy
Colposcopy and computer graphics (Fegerl). 1990;162:1347-8 (Letter)
The computerized digital imaging colposcope: future directions (Crisp et al). 1990;162:1491-8
Remarks deemed overly critical of research by private practice physicians (Davison) (Letter); (Reid) (Reply). 1990;162:290-1
Treatment of cervical intraepithelial neoplasia: experience with the low-voltage diathermy loop (Whiteley and Oláh). 1990;162:1272-7
Community hospitals; *see* **Hospitals, community**
Compartment syndrome
Bilateral compartment syndrome after a long gynecologic operation in the lithotomy position (Adler et al). 1990;162:1271-2
Compliance
Conclusions lack support (Goodlin) (Letter); (Mueller-Heubach) (Reply). 1990;162:1627-8
Computer graphics
Colposcopy and computer graphics (Fegerl). 1990;162:1347-8 (Letter)
The computerized digital imaging colposcope: future directions (Crisp et al). 1990;162:1491-8
Condyloma acuminata
Intralesional interferon alfa-2b for the treatment of genital warts (Welander et al). 1990;162:348-54
Congenital adrenal hyperplasia; *see* **Adrenal hyperplasia, congenital**
Consumer satisfaction
Use of the labor-delivery-recovery room in an urban tertiary care hospital (Williams and Mervis). 1990;162:23-4
Contraceptives, oral
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103
Oral contraceptives and infection rates (Grimes and Mishell) (Letter); (Louv et al) (Reply). 1990;162:1121-2
Contraceptives, oral, hormonal
Hormonal contraception in the postmolar interval (Yuen and Callegari). 1990;162:1345 (Letter)
Cordocentesis; *see* **Fetal blood**
Corrections
Effect of pregnancy on uterine and carotid artery response to norepinephrine, epinephrine, and phenylephrine in vessels with documented functional endothelium (Weiner et al) (1989;161:1605-10). 1990;162:1133
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al) (1990;162:382-6). 1990;162:1363
Correspondence
Letters. 1990;162:288-98, 596-609, 865-77, 1121-33, 1138-63, 1625-44
Corticosteroids; *see* **Adrenal cortex hormones**
Corticotropin-releasing hormone
Immunoreactive corticotropin-releasing hormone in amniotic fluid (Sasaki et al). 1990;162:194-8
Spontaneous resolution of Cushing's syndrome after pregnancy (Aron et al). 1990;162:472-4
Cost benefit analysis
Postpartum gentamicin dosing and endometritis (Stoukides and Souney) (Letter); (Briggs et al) (Reply). 1990;162:1132-3
Cross sectional studies
A longitudinal study of respiratory changes in normal human pregnancy with cross-sectional data on subjects with pregnancy-induced hypertension (Rees et al). 1990;162:826-30
Cryopreservation
Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting (DiMarzo et al). 1990;162:1483-90
Cul-de-sac of Douglas; *see* **Douglas' pouch**
Culdocentesis; *see* **Fallopian tubes, surgery**
Culture media
GBS-test sensitivity questioned (Lester et al) (Letter); (Christensen and Christensen) (Reply). 1990;162:291

Curettage
Diagnostic and therapeutic curettage in gestational trophoblastic disease (Schlaerth et al). 1990;162:1465-71
Prediction of residual trophoblastic tissue in first-trimester abortions and low levels of human chorionic gonadotropin β-subunit (Schiff et al). 1990;162:797-801
Current developments
Current developments. 1990;162:244-52, 502-14, 809-18, 1073-83
Current investigation
Current investigation. 1990;162:495-501
Cushing's syndrome
Cushing's syndrome and pregnancy (Aron et al). 1990;162:244-52 (Curr. dev.)
Spontaneous resolution of Cushing's syndrome after pregnancy (Aron et al). 1990;162:472-4
Cystadenoma
Case of retroperitoneal mucinous cystadenoma omitted (Cruikshank) (Letter); (Pennell) (Reply). 1990;162:1351-3
Coexistence of mucinous cystadenoma of the ovary and ovarian sarcoidosis (White et al). 1990;162:1284-5
Cystoscopy
Modified cystoscopy to evaluate unilateral traumatic injury of the ureter during pelvic surgery (Lin and Iwata). 1990;162:1343-4 (Letter)
Cysts
Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6
Cytogenetics
Ammonium chloride pretreatment of bloody amniotic fluids for cytogenetic analysis (Macera et al). 1990;162:868-70 (Letter)
Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6
Cytogenetic results of chorionic villus sampling: high success rate and diagnostic accuracy in the United States collaborative study (Ledbetter et al). 1990;162:495-501 (Curr. invest.)
Cytomegaloviruses
Fetal cytomegalovirus infection: a case report (Meisel et al). 1990;162:663-4
Cytoplasm
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8
Cytotoxicity
Lack of association of cytotoxicity in serum and preeclampsia (Frohlich) (Letter); (Roberts and Taylor) (Reply). 1990;162:873-4

D

Danazol
Comparison of the pharmacology of nafarelin and danazol (Barbieri). 1990;162:581-5 (Symposium)
Effects of nafarelin versus danazol on lipids and calcium metabolism (Bergquist). 1990;162:589-91 (Symposium)
Efficacy and safety of nafarelin in the treatment of endometriosis (Henzl and Kwei). 1990;162:570-4 (Symposium)
Insulin-dependent diabetes mellitus associated with danazol (Seifer et al). 1990;162:474-5
Nafarelin in the treatment of pelvic pain caused by endometriosis (Shaw). 1990;162:574-6 (Symposium)
Nafarelin versus danazol in the treatment of endometriosis (Rolland and van der Heijden). 1990;162:586-8 (Symposium)
Decidua
Immunocytochemical localization and messenger ribonucleic acid concentrations for human placental lactogen in amnion, chorion, decidua, and placenta (Sakbun et al). 1990;162:1310-7
Decision making
Men without chests (Maxwell). 1990;162:1499-501 (Pres. address)
Vaginal birth after cesarean or repeat cesarean section: Medical risks or social realities? (Kirk et al). 1990;162:1398-405
Deep venous thrombosis; *see* **Thromboembolism**
Delivery
Birth stress increases fetal atrial natriuretic factor (Andersson et al) (Letter); (Cheung and Brace) (Reply). 1990;162:872-3
The case for routine umbilical blood acid-base studies at delivery (Johnson et al). 1990;162:621-5 (Clin. opinion)
Changes in hemostasis activity during delivery and the immediate postpartum period (Gerbasi et al). 1990;162:1158-63
A comparison of the morbidity of midforceps and cesarean delivery (Bashore et al). 1990;162:1428-35
Different characteristics of amniotic and cervical collagenous tissue during pregnancy and delivery: a morphologic study (Yoshida and Manabe). 1990;162:190-3
The efficacy of external cephalic version and its impact on the breech experience (Hanss). 1990;162:1459-64
Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries (Robertson et al). 1990;162:1436-44
Perinatal factors associated with the respiratory distress syndrome (Bryan et al). 1990;162:476-81
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Successful pregnancy and normal delivery with Marlex mesh replacement of the abdominal wall (Ezra et al). 1990;162:97-8
Thrombocytopenia at delivery: a prospective survey of 6715 deliveries (Burrows and Kelton). 1990;162:731-4
Vaginal birth after cesarean or repeat cesarean section: Medical risks or social realities? (Kirk et al). 1990;162:1398-405
Delivery rooms
Use of the labor-delivery-recovery room in an urban tertiary care hospital (Williams and Mervis). 1990;162:23-4
Demography
Effects of birth weight and sociodemographic variables on mental development of neonatal intensive care unit survivors (Resnick et al). 1990;162:374-8
Deoxyribonucleic acid; *see* **DNA**
Diabetes mellitus, insulin-dependent; *see also* **Pregnancy in diabetes**
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Insulin-dependent diabetes mellitus associated with danazol (Seifer et al). 1990;162:474-5
Diagnosis, computer-assisted
The computerized digital imaging colposcope: future directions (Crisp et al). 1990;162:1491-8
Diagnosis, differential
Diagnosis and clinical presentation of endometriosis (Adamson). 1990;162:568-9 (Symposium)

Diagnosis, differential—cont'd
Statistical evaluation of diagnostic criteria for bacterial vaginosis (Thomason et al). 1990;162:155-60
Diagnosis, laboratory
The ferning test for detection of amniotic fluid contamination in umbilical blood samples (Chao et al). 1990;162:1207-13
Diathermy
Treatment of cervical intraepithelial neoplasia: experience with the low-voltage diathermy loop (Whiteley and Oláh). 1990;162:1272-7
Diethylstilbestrol
Vaginal bleeding and diethylstilbestrol exposure during pregnancy: relationship to genital tract clear cell adenocarcinoma and vaginal adenosis in daughters (Sharp and Cole). 1990;162:994-1001
Digoxin
Use of digoxin in pregnancy (De Lia and Emery) (Letter); (Weiner) (Reply). 1990;162:606-8
Digoxin-like immunoreactive substances; *see* **Antibodies**
Dilatation
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
Diphosphoglyceric acid
The relationship of maternal erythrocyte oxygen transport parameters to intrauterine growth retardation (Brown et al). 1990;162:223-9
Disopyramide
The effect of disopyramide on uterine contractions during pregnancy (Tadmor et al). 1990;162:482-6
Disseminated intravascular coagulation
Disseminated intravascular coagulopathy and adult respiratory distress syndrome: life-threatening complications of hysteroscopy (Jedeikin et al). 1990;162:44-5
DNA
Deoxyribonucleic acid flow cytometric analysis of cervical adenocarcinoma: prognostic significance of deoxyribonucleic acid ploidy and S-phase fraction (Leminen et al). 1990;162:848-53
Underwear: contamination by human papillomaviruses (Bergeron et al). 1990;162:25-9
DNA probes
Screening of seven putative 45,X subjects with deoxyribonucleic acid probes to detect low-level mosaicism for Y cell lines (Tho et al). 1990;162:59-60
DNA probes, HPV
Effect of the menstrual cycle on detection and typing of human papillomavirus in uterine cervical cells (McNicol et al). 1990;162:1037-41
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103
Domiciliary fetal monitoring; *see* **Fetal monitoring**
Dopamine
Plasma atrial natriuretic factor and urinary excretion of a ouabain displacing factor and dopamine in normotensive pregnant women before and after delivery (Gregoire et al). 1990;162:71-6
Doppler echocardiography; *see* **Echocardiography, Doppler**
Doppler ultrasound; *see* **Ultrasonic diagnosis**
Doppler velocimeters; *see* **Flowmeters**
Douglas' pouch
A new method for gaining entry into the scarred anterior cul-de-sac during transvaginal hysterectomy (Hoffman and Jaeger). 1990;162:1269-70
Down's syndrome
Biparietal diameter/femur length ratio as predictor of trisomy 21 (Kopelman and Miyazawa). 1990;162:1346 (Letter)
Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52
Maternal serum Down syndrome screening: unconjugated estriol is not useful (Macri et al). 1990;162:672-3
Maternal serum α-fetoprotein screening for fetal Down syndrome in the United States: results of a survey (Palomaki et al). 1990;162:317-21
Measurement of unconjugated estriol by enzyme-linked immunosorbent assay fails to show an association with Down syndrome (Macri et al). 1990;162:1634-5 (Letter)
Ductus arteriosus
The effect of indomethacin on the pulsatility index of the umbilical artery in human fetuses (Moise et al). 1990;162:199-202
Placental transfer of indomethacin in the human pregnancy (Moise et al). 1990;162:549-54
Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10
Dystocia
Shoulder dystocia: prevention and treatment (O'Leary and Leonetti). 1990;162:5-9 (Clin. opinion)
The Zavanelli maneuver (Dimitry). 1990;162:1343 (Letter)

E

Echocardiography, Doppler
Prenatal diagnosis of valvar aortic stenosis by Doppler echocardiography and magnetic resonance imaging (Hata et al). 1990;162:1068-70
Echoencephalography
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
Eclampsia
Magnesium sulfate is the ideal anticonvulsant in preeclampsia-eclampsia (Sibai). 1990;162:1141-5 (Clin. opinion)
Reliance on central venous pressure with regard to fluid management in preeclampsia deemed dangerous (Clark). 1990;162:598 (Letter)
Ectopic pregnancy; *see* **Pregnancy, ectopic**
Editorial
Editorial. 1990;162:613-4
Education, medical, graduate
Journal article appraisal (Capecchi). 1990;162:1121 (Letter)
Scientific advances, societal trends, and the education and practice of obstetrician-gynecologists (Willson). 1990;162:1135-40 (Clin. opinion)
Electrodiagnosis
Is pH test paper as accurate as the electronic measurement of the pH of vaginal secretions? (Thomason et al). 1990;162:1213-4
Electrolytes
Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention (Crombleholme et al). 1990;162:1239-44
Electron spin resonance
Studies on cervical intraepithelial neoplasia: the level of octadeca-9,11-dienoic acid and measurement of free radical content by electron spin resonance spectroscopy (Wickens et al). 1990;162:854-8

Electrotherapy
The conservative management of patients with symptoms of stress incontinence: a randomized, prospective study comparing weighted vaginal cones and interferential therapy (Oláh et al). 1990;162:87-92
Embolization, therapeutic
Angiographic embolization (Heffner) (Letter); (Chin) (Reply). 1990;162:1345-6
Embryo
Does previous *Chlamydia trachomatis* infection influence the pregnancy rate of in vitro fertilization and embryo replacement (Osser et al). 1990;162:40-4
Embryoscopy: description and utility of a new technique (Cullen et al). 1990;162:82-6
Uterine large granular lymphocytes: A possible role in embryonic implantation? (King and Loke). 1990;162:308-10 (Clin. opinion)
Embryo, animal
Studies of hexokinase activity in human and mouse oocyte (Tsutsumi et al). 1990;162:1301-4
Embryo, preimplantation, animal; *see* Blastocyst, animal
Embryoscopy; *see* Chorionic villi sampling
Enalapril
Oligohydramnios sequence and renal tubular malformation associated with maternal enalapril use (Cunniff et al). 1990;162:187-9
Encephalomalacia
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
Endocervicitis; *see* Cervix diseases
Endodermal sinus tumor; *see* Mesonephroma
Endometrial adenocarcinoma; *see* Adenocarcinoma
Endometrial neoplasms; *see* Uterine neoplasms
Endometriosis
CA 125 in peritoneal fluid (Williams) (Letter); (Dawood et al) (Reply). 1990;162:296
Comparison of the pharmacology of nafarelin and danazol (Barbieri). 1990;162:581-5 (Symposium)
Diagnosis and clinical presentation of endometriosis (Adamson). 1990;162:568-9 (Symposium)
Effects of nafarelin on bone density (Jacobson). 1990;162:591-2 (Symposium)
Efficacy and safety of nafarelin in the treatment of endometriosis (Henzl and Kwei). 1990;162:570-4 (Symposium)
Etiology and epidemiology of endometriosis (Barbieri). 1990;162:565-7 (Symposium)
Evaluation of hysteroscopic management of the septate uterus (Simpson). 1990;162:598-9 (Letter)
Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy (Barbieri). 1990;162:593-5 (Symposium)
Gonadotropin-releasing hormone analogs in the treatment of endometriomas (Schenken). 1990;162:579-81 (Symposium)
Insulin-dependent diabetes mellitus associated with danazol (Seifer et al). 1990;162:474-5
Nafarelin in the treatment of infertility caused by endometriosis (Barlow). 1990;162:576-9 (Symposium)
Nafarelin in the treatment of pelvic pain caused by endometriosis (Shaw). 1990;162:574-6 (Symposium)
Nafarelin versus danazol in the treatment of endometriosis (Rolland and van der Heijden). 1990;162:586-8 (Symposium)
Endometritis
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43
Pneumatometra (Muram et al). 1990;162:1282-3
Postpartum gentamicin dosing and endometritis (Stoukides and Souney) (Letter); (Briggs et al) (Reply). 1990;162:1132-3
Endometrium
Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—preliminary data (Raman et al). 1990;162:1511-7
Endometrial involution (Ritter and Philippe) (Letter); (Check) (Reply). 1990;162:1360-1
Estrogen replacement therapy and the risk of endometrial cancer: remaining controversies (Rubin et al). 1990;162:148-54
Evaluation of unfavorable histologic subtypes in endometrial adenocarcinoma (Wilson et al). 1990;162:418-26
The impact of luteal phase inadequacy in an infertile population (Wentz et al). 1990;162:937-45
In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14
Endometrium, animal
Designing a schedule of progestin administration in the control of endometrial carcinoma growth in the nude mouse model (Mortel et al). 1990;162:928-36
Endoscopy
Embryoscopy: description and utility of a new technique (Cullen et al). 1990;162:82-6
Endothelin
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8
Endothelium
Increased plasma levels of ED1$^+$ cellular fibronectin precede the clinical signs of preeclampsia (Lockwood and Peters). 1990;162:358-62
Pathophysiology of antiphospholipid antibodies: absence of prostaglandin-mediated effects on cultured endothelium (Dudley et al). 1990;162:953-9
Endothelium, vascular
Anti-vascular endothelial cell antibodies in severe preeclampsia (Rappaport et al). 1990;162:138-46
Endovaginal ultrasonography; *see* Ultrasonic diagnosis
Enzyme activation
The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
Enzyme-linked immunosorbent assay
Measurement of unconjugated estriol by enzyme-linked immunosorbent assay fails to show an association with Down syndrome (Macri et al). 1990;162:1634-5 (Letter)
Epidemiology
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)
Epidermal growth factor-urogastrone
Immunohistochemical localization of epidermal growth factor receptor during implantation in the rabbit (Hofmann and Anderson). 1990;162:837-41

Epidural analgesia; *see* Analgesia, epidural
Epithelium
Heterogeneity of antigen expression in advanced epithelial ovarian cancer (Berchuck et al). 1990;162:883-8
Erythroblastosis, fetal
Blood gas studies in fetal heart blood (Soothill) (Letter); (Westgren) (Reply). 1990;162:1636-7
Doppler examination of the middle cerebral artery in anemic fetuses (Vyas et al). 1990;162:1066-8
Efficacy of management of isoimmunization with fetal umbilical blood sampling remains unproved (Deveny and Lenke). 1990;162:297-8 (Letter)
Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4
Intrauterine transfusion—intraperitoneal versus intravascular approach: a case-control comparison (Harman et al). 1990;162:1053-9
Management of isoimmunized pregnancy by use of intravascular techniques (Porto et al) (Letter); (Barss) (Reply). 1990;162:292-3
Prediction of fetoplacental blood volume in isoimmunized pregnancy (Leduc and Moise) (Letter); (MacGregor) (Reply). 1990;162:1124
Reply to Weiner (1989;161:1091-2) (Daffos). 1990;162:298 (Letter)
Resolution of severe thrombocytopenia in a pregnant patient with rhesus-negative blood with autoimmune thrombocytopenic purpura after intravenous rhesus immune globulin (Moise et al). 1990;162:1237-8
Use of cordocentesis in fetal hemolytic disease and autoimmune thrombocytopenia (Weiner) (Letter); (Reece et al) (Reply). 1990;162:1126-8
Vel isoimmunization in pregnancy (Stiller et al). 1990;162:1071-2
Erythromycin
Clindamycin therapy for *Chlamydia trachomatis* in women (Campbell and Dodson). 1990;162:343-7
Estradiol
Placental production of estradiol and progesterone after oocyte donation in patients with primary ovarian failure (Devroey et al). 1990;162:66-70
In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14
Estriol
Maternal serum Down syndrome screening: unconjugated estriol is not useful (Macri et al). 1990;162:672-3
Measurement of unconjugated estriol by enzyme-linked immunosorbent assay fails to show an association with Down syndrome (Macri et al). 1990;162:1634-5 (Letter)
Estrogen antagonists
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
Estrogen replacement therapy
Estrogen replacement therapy and the risk of endometrial cancer: remaining controversies (Rubin et al). 1990;162:148-54
Evaluation of a continuous combined low-dose regimen of estrogen-progestin for treatment of the menopausal patient (Weinstein et al). 1990;162:1534-42
Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy (Barbieri). 1990;162:593-5 (Symposium)
Estrogens
The antiestrogenic effect of cigarette smoking in women (Baron et al). 1990;162:502-14 (Curr. dev.)
Etiology and epidemiology of endometriosis (Barbieri). 1990;162:565-7 (Symposium)
Evaluation of a continuous combined low-dose regimen of estrogen-progestin for treatment of the menopausal patient (Weinstein et al). 1990;162:1534-42
Hormone activity and autoimmune function (Pun and Ho) (Letter); (Gleicher and El-Roeiy) (Reply). 1990;162:866-7
A study of combined continuous ethinyl estradiol and norethindrone acetate for postmenopausal hormone replacement (Williams et al). 1990;162:438-46
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
Transcapillary fluid dynamics during ovarian stimulation for in vitro fertilization (Tollan et al). 1990;162:554-8
Ethics, medical
Clinical guides to preventing ethical conflicts between pregnant women and their physicians (Chervenak and McCullough). 1990;162:303-7 (Clin. opinion)
Ethics and reproduction (Macnaughton). 1990;162:879-82
Men without chests (Maxwell). 1990;162:1499-501 (Pres. address)
Ethinyl estradiol
A study of combined continuous ethinyl estradiol and norethindrone acetate for postmenopausal hormone replacement (Williams et al). 1990;162:438-46
Etoposide
Gestational trophoblastic disease: What have we learned in the past decade? (Jones). 1990;162:1286-95
Exencephaly; *see* Anencephaly
Exercise
Comparative evaluation of uterine response to exercise on five aerobic machines (Durak et al). 1990;162:754-6
Theoretical and technical questions involved with hemodynamic responses (Clapp) (Letter); (Morrow) (Reply). 1990;162:867-8
Exercise test
Assessment of fetal response to exercise in pregnancy (Rafla) (Letter); (Morrow) (Reply). 1990;162:1129-30
Cardiovascular response to maximal cycle exercise during pregnancy and at two and seven months post partum (Sady et al). 1990;162:1181-5
Expenditures, health
The tyranny of technology (Figge). 1990;162:1365-9 (Pres. address)

F

Fabry's disease; *see* Angiokeratoma corporis diffusum
Fallopian tubes, surgery
Reevaluation of the role of culdocentesis in the management of ectopic pregnancy (Vermesh et al). 1990;162:411-3
Familial hypercholesterolemia; *see* Hypercholesterolemia, familial
Fasting
Accelerated starvation in late pregnancy: a comparison between obese women with and without gestational diabetes mellitus (Buchanan et al). 1990;162:1015-20

Fatty liver
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
Fecundity; *see* **Fertility**
Feedback
Feedback mechanism of human chorionic gonadotropin secretion (Dericks-Tan and Taubert). 1990;162:608-9 (Letter)
Femur
Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52
Ferning test; *see* **Diagnosis, laboratory**
Fertility; *see also* **Infertility, female; Infertility, male**
Conservative management of cervical pregnancy with subsequent fertility (Bachus et al). 1990;162:450-1
The impact of luteal phase inadequacy in an infertile population (Wentz et al). 1990;162:937-45
Value of hamster egg penetration assay (Corson) (Letter); (Mao and Grimes) (Reply). 1990;162:865
Fertility agents
Selective termination: clinical experience and residual risks (Evans et al). 1990;162:1568-75
Fertilization
Reproductive performance after methotrexate treatment of ectopic pregnancy (Stovall et al). 1990;162:1620-4
Fertilization in vitro
Does previous *Chlamydia trachomatis* infection influence the pregnancy rate of in vitro fertilization and embryo replacement (Osser et al). 1990;162:40-4
Selective termination: clinical experience and residual risks (Evans et al). 1990;162:1568-75
Transcapillary fluid dynamics during ovarian stimulation for in vitro fertilization (Tollan et al). 1990;162:554-8
Fertilization in vitro, animal
The effect of prolactin on murine in vitro fertilization and embryo development (Dodds et al). 1990;162:1553-61
Fetal alloimmunization; *see* **Erythroblastosis, fetal**
Fetal anemia; *see* **Anemia**
Fetal anoxia, animal
Intrauterine asphyxia and the breakdown of physiologic circulatory compensation in fetal sheep (Block et al). 1990;162:1325-31
Fetal asphyxia; *see* **Asphyxia neonatorum**
Fetal auditory perception; *see* **Auditory perception**
Fetal biophysical profile; *see* **Fetal monitoring**
Fetal blood
Abruptio placentae after percutaneous umbilical cord sampling: a case report (Feinkind et al). 1990;162:1203-4
Antepartum heart rate patterns in small-for-gestational-age third-trimester fetuses: correlations with blood gas values obtained at cordocentesis (Visser et al). 1990;162:698-703
Assessment of fetal response to exercise in pregnancy (Rafla) (Letter); (Morrow) (Reply). 1990;162:1129-30
Blood gas studies in fetal heart blood (Soothill) (Letter); (Westgren) (Reply). 1990;162:1636-7
Blood sampling and transfusion in utero suggested in the pumping twin (Jakobi and Zimmer) (Letter); (Stiller and Romero) (Reply). 1990;162:1632-3
Calculation of fetoplacental volume (Moise). 1990;162:596 (Letter)
The case for routine umbilical blood acid-base studies at delivery (Johnson et al). 1990;162:621-5 (Clin. opinion)
Changes in blood gas, acid-base parameters require adjustment (Soothill) (Letter); (Ferrazzi et al) (Reply). 1990;162:1350-1
Chronic, massive fetomaternal hemorrhage treated with repeated fetal intravascular transfusions (Fischer et al). 1990;162:203-4
Cordocentesis for rapid karyotyping (Shah et al). 1990;162:1548-53
Doppler examination of the middle cerebral artery in anemic fetuses (Vyas et al). 1990;162:1066-8
Doppler measurements of fetal and uteroplacental circulations: relationship with umbilical venous blood gases measured at cordocentesis (Bilardo et al). 1990;162:115-20
Efficacy of management of isoimmunization with fetal umbilical blood sampling remains unproved (Deveny and Lenke). 1990;162:297-8 (Letter)
The ferning test for detection of amniotic fluid contamination in umbilical blood samples (Chao et al). 1990;162:1207-13
Fetal umbilical blood gas values as diagnostic criteria (Weiner) (Letter); (Warren et al) (Reply). 1990;162:1124-5
Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al). 1990;162:382-6
Is sampling technique beneficial to fetus? (Lenke and Deveny) (Letter); (Scioscia et al) (Reply). 1990;162:597-8
Platelet count in normal, small, and anemic fetuses (Van den Hof and Nicolaides). 1990;162:735-9
Prediction of fetal anemia by measurement of the mean blood velocity in the fetal aorta (Nicolaides et al). 1990;162:209-12
Prediction of fetoplacental blood volume in isoimmunized pregnancy (Leduc and Moise) (Letter); (MacGregor) (Reply). 1990;162:1124
Relation of rate of urine production to oxygen tension in small-for-gestational-age fetuses (Nicolaides et al). 1990;162:387-91
The relationship between the umbilical artery systolic/diastolic ratio and umbilical blood gas measurements in specimens obtained by cordocentesis (Weiner). 1990;162:1198-202
Reply to Weiner (1989;161:1091-2) (Daffos). 1990;162:298 (Letter)
Use of cordocentesis in fetal hemolytic disease and autoimmune thrombocytopenia (Weiner) (Letter); (Reece et al) (Reply). 1990;162:1126-8
Fetal blood, animal
Direct determination of the ovine fetal umbilical artery blood flow waveform (Irion and Clark). 1990;162:541-9
Fetal hemodynamic and fetoplacental vascular response to exogenous arginine vasopressin (Irion et al). 1990;162:1115-20
Local cerebral blood flow is increased in rapid-eye-movement sleep in fetal sheep (Abrams et al). 1990;162:278-81
Nuchal muscle activity at different levels of hypoxemia in fetal sheep (Woudstra et al). 1990;162:559-64
Umbilical amino acid concentrations in normal and growth-

Fetal blood, animal—cont'd
retarded fetuses sampled in utero by cordocentesis (Cetin et al). 1990;162:253-61
Fetal death
Corticosteroid treatment of pregnant women with antiphospholipid antibodies and previous fetal loss (Lubbe and Pattison) (Letter); (Lockshin and Druzin) (Reply). 1990;162:1341-3
Efficacy of prednisone treatment to prevent recurrent fetal death (Cowchock and Balaban) (Letter); (Lockshin et al) (Reply). 1990;162:1128-9
Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality (Manning et al). 1990;162:703-9
Maternal reproductive histories in ataxic cerebral palsy (Miller). 1990;162:242-3
Maternal spermicide use and adverse reproductive outcome: a meta-analysis (Einarson et al). 1990;162:655-60
A model for the prospective analysis of perinatal deaths in a perinatal network (Moawad et al). 1990;162:15-22
Need for a prospective treatment trial (Harris). 1990;162:1121 (Letter)
Fetal development
Biparietal diameter/femur length ratio as predictor of trisomy 21 (Kopelman and Miyazawa). 1990;162:1346 (Letter)
Birth weight discordancy in male-first and female-first pairs of unlike-sexed twins (Blickstein and Weissman). 1990;162:661-3
Evaluation of the lemon and banana signs in one hundred thirty fetuses with open spina bifida (Van den Hof et al). 1990;162:322-7
Fetal assessment based on fetal biophysical profile scoring. III. Positive predictive accuracy of the very abnormal test (biophysical profile score = 0) (Manning et al). 1990;162:398-402
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al). 1990;162:382-6
Intrapartum asphyxia in the preterm fetus <2000 gm (Low et al). 1990;162:378-82
Intrauterine fetal growth in concordant twin gestations (Rodis et al). 1990;162:1025-9
Maternal serum α-fetoprotein levels in pregnancies among black and white women with fetal open spina bifida: a United States Collaborative Study (Johnson et al). 1990;162:328-31
Maternal serum α-fetoprotein screening for fetal Down syndrome in the United States: results of a survey (Palomaki et al). 1990;162:317-21
Mathematic form corrected (Habekovic) (Letter); (Sabbagha) (Reply). 1990;162:1351
Seventy-one quadruplet pregnancies: management and outcome (Collins and Bleyl). 1990;162:1384-92
Fetal development, abnormalities; *see* **Fetus, abnormalities**
Fetal development, animal
Functional tolerance to the effects of ethanol on fetal biophysical activities? (Smith et al) (Letter); (Castillo and Devoe) (Reply). 1990;162:1631-2
Sound environment of the fetal sheep (Gerhardt et al). 1990;162:282-7
Fetal diseases
Predicting neonatal morbidity after perinatal asphyxia: a scoring system (Portman et al). 1990;162:174-82
Fetal distress
Birth stress increases fetal atrial natriuretic factor (Anderson et al) (Letter); (Cheung and Brace) (Reply). 1990;162:872-3
An evaluation of the efficacy of Doppler flow velocity waveform analysis as a screening test in pregnancy (Newnham et al). 1990;162:403-10
Fetal acoustic stimulation in the early intrapartum period as a predictor of subsequent fetal condition (Sarno et al). 1990;162:762-7
Prenatal diagnosis of intracerebellar hemorrhage: case report (Jennett et al). 1990;162:1472-5
Prophylactic intrapartum amnioinfusion: a randomized clinical trial (Strong et al). 1990;162:1370-5
A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9
What is fetal distress? (Parer and Livingston). 1990;162:1421-7
Fetal growth retardation
An evaluation of the efficacy of Doppler flow velocity waveform analysis as a screening test in pregnancy (Newnham et al). 1990;162:403-10
Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52
Intrauterine growth retardation and preterm delivery: prenatal risk factors in an indigent population (Wen et al). 1990;162:213-8
Intrauterine growth retardation is not the same as small for gestational age (Goodlin) (Letter); (Goldenberg et al) (Reply). 1990;162:1642-3
Middle cerebral artery blood flow in normal and growth-retarded fetuses (Veille and Cohen). 1990;162:391-6
Neonatal growth assessment score: a new approach to the detection of intrauterine growth retardation in the newborn (Deter et al). 1990;162:1030-6
Platelet count in normal, small, and anemic fetuses (Van den Hof and Nicolaides). 1990;162:735-9
Poor predictive value of symphysial-fundal height when misused in clinical practice (Belizan et al). 1990;162:1348-9 (Letter)
The relationship of maternal erythrocyte oxygen transport parameters to intrauterine growth retardation (Brown et al). 1990;162:223-9
Severe symmetric intrauterine growth retardation associated with the topical use of triamcinolone (Katz et al). 1990;162:396-7
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Umbilical amino acid concentrations in normal and growth-retarded fetuses sampled in utero by cordocentesis (Cetin et al). 1990;162:253-61
The value of Doppler assessment of the uteroplacental circulation in predicting preeclampsia or intrauterine growth retardation (Jacobson et al). 1990;162:110-4
Fetal heart
Placental transfer of indomethacin in the human pregnancy (Moise et al). 1990;162:549-54
Fetal heart, animal
Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10
Fetal heart rate; *see* **Heart rate, fetal**
Fetal hemoglobin
Blood sampling and transfusion in utero suggested in the pumping twin (Jakobi and Zimmer) (Letter); (Stiller and Romero) (Reply). 1990;162:1632-3

Chronic, massive fetomaternal hemorrhage treated with repeated fetal intravascular transfusions (Fischer et al). 1990;162:203-4
Platelet count in normal, small, and anemic fetuses (Van den Hof and Nicolaides). 1990;162:735-9
Prediction of fetal anemia by measurement of the mean blood velocity in the fetal aorta (Nicolaides et al). 1990;162:209-12

Fetal lung maturity; *see* Fetal organ maturity

Fetal macrosomia

Macrosomia: influence of maternal overweight among a low-income population (Larsen et al). 1990;162:490-4
Ultrasonographic estimation of fetal weight in the clinically macrosomic fetus (Hirata et al). 1990;162:238-42

Fetal membranes

Mechanisms of parturition: the transfer of prostaglandin E_2 and 5-hydroxyeicosatetraenoic acid across fetal membranes (Bennett et al). 1990;162:683-7
Perinatal factors associated with the respiratory distress syndrome (Bryan et al). 1990;162:476-81
Significance of observing no fluid at amniotomy (Druzin and Adams). 1990;162:1006-7

Fetal membranes, premature rupture

Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9
An analysis of antenatal tests to detect infection in preterm premature rupture of the membranes (Ohlsson and Wang). 1990;162:809-18 (Curr. dev.)
Chlamydia trachomatis infection in pregnancy and effect of treatment on outcome (Ryan et al). 1990;162:34-9
Detection of platelet-activating factor in amniotic fluid of complicated pregnancies (Hoffman et al). 1990;162:525-8
The ferning test for detection of amniotic fluid contamination in umbilical blood samples (Chao et al). 1990;162:1207-13
Is obstetric progress dependent on rigorous randomized controlled trials? (Goodlin) (Letter); (Ohlsson) (Reply). 1990;162:1353-5
Neonatal outcome after prolonged preterm rupture of the membranes (Rotschild et al). 1990;162:46-52
Symptoms that precede preterm labor and preterm premature rupture of the membranes (Iams et al). 1990;162:486-90

Fetal monitoring

The abnormal fetal biophysical profile score. V. Predictive accuracy according to score composition (Manning et al). 1990;162:918-27
Effects of hypoxemia with and without acidemia on the isometric contraction time and the electromechanical delay of the fetal myocardium: an experimental study on the ovine fetus (Fouron et al). 1990;162:262-6
Fetal acoustic stimulation in the early intrapartum period as a predictor of subsequent fetal condition (Sarno et al). 1990;162:762-7
Fetal assessment based on fetal biophysical profile scoring. III. Positive predictive accuracy of the very abnormal test (biophysical profile score = 0) (Manning et al). 1990;162:398-402
Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality (Manning et al). 1990;162:703-9
Functional tolerance to the effects of ethanol on fetal biophysical activities? (Smith et al) (Letter); (Castillo and Devoe) (Reply). 1990;162:1631-2
Limitations of antenatal fetal heart rate monitors (Dawes et al). 1990;162:170-3
Patient-recorded domiciliary fetal monitoring (Lindsay et al). 1990;162:466-70
Theoretical and technical questions involved with hemodynamic responses (Clapp) (Letter); (Morrow) (Reply). 1990;162:867-8
What is fetal distress? (Parer and Livingston). 1990;162:1421-7

Fetal movement

Caution regarding fetal acoustic stimulation in oligohydramnios (Menashe and Sherer) (Letter); (Ingemarsson and Arulkumaran) (Reply). 1990;162:603-4

Fetal movement, animal

Nuchal muscle activity at different levels of hypoxemia in fetal sheep (Woudstra et al). 1990;162:559-64

Fetal organ maturity

Neonatal outcome after prolonged preterm rupture of the membranes (Rotschild et al). 1990;162:46-52
Oligohydramnios sequence and renal tubular malformation associated with maternal enalapril use (Cunniff et al). 1990;162:187-9
Rabbit alveolar β-adrenergic receptors increase with gestational age (Lewis et al). 1990;162:269-72
The tap test: confirmation of a simple, rapid, inexpensive, and reliable indicator of fetal pulmonary maturity (Socol). 1990;162:218-22

Fetal sex; *see* Sex, infant

Fetal transfusion; *see* Blood transfusion, intrauterine

Fetal viability

Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities (Check et al). 1990;162:674-5

Fetofetal transfusion

Blood sampling and transfusion in utero suggested in the pumping twin (Jakobi and Zimmer) (Letter); (Stiller and Romero) (Reply). 1990;162:1632-3

Fetomaternal hemorrhage; *see* Fetomaternal transfusion

Fetomaternal transfusion

Chronic, massive fetomaternal hemorrhage treated with repeated fetal intravascular transfusions (Fischer et al). 1990;162:203-4
Fetomaternal transfusion depends on amount of chorionic villi aspirated but not on method of chorionic villus sampling (Shulman et al). 1990;162:1185-8
Pregnancy outcome and fetomaternal hemorrhage after noncatastrophic trauma (Goodwin and Breen). 1990;162:665-71
A prospective controlled study of outcome after trauma during pregnancy (Pearlman et al). 1990;162:1502-10

Fetoplacental blood; *see* Fetal blood

Fetoplacental function tests; *see* Placental function tests

Fetus, abnormalities

Early prenatal diagnosis of gastroschisis with transvaginal ultrasonography (Guzman). 1990;162:1253-4
Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention (Crombleholme et al). 1990;162:1239-44
Hydramnios in the third trimester of pregnancy: a change in the distribution of accompanying fetal anomalies as a result of early ultrasonographic prenatal diagnosis (Ben-Chitrit et al). 1990;162:1344-5 (Letter)

Fetus, abnormalities—cont'd
Sonographic findings in the prenatal diagnosis of bladder exstrophy (Jaffe et al). 1990;162:675-8
Fibroma
Successful pregnancy and normal delivery with Marlex mesh replacement of the abdominal wall (Ezra et al). 1990;162:97-8
Fibronectins
Anti-vascular endothelial cell antibodies in severe preeclampsia (Rappaport et al). 1990;162:138-46
Increased plasma levels of ED1$^+$ cellular fibronectin precede the clinical signs of preeclampsia (Lockwood and Peters). 1990;162:358-62
First European Conference on Sex Steroids and Metabolism
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)
First trimester pregnancy; *see* **Pregnancy trimester, first**
Flow cytometry
Flow cytometric evaluation of epithelial ovarian cancer (Barnabei et al). 1990;162:1584-92
Flowmeters
A comparison between umbilical artery velocimetry and standard antepartum surveillance in hospitalized high-risk patients (Lowery et al). 1990;162:710-4
The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: a prospective blinded study (Maulik et al). 1990;162:1518-25
An evaluation of the efficacy of Doppler flow velocity waveform analysis as a screening test in pregnancy (Newnham et al). 1990;162:403-10
Middle cerebral artery blood flow in normal and growth-retarded fetuses (Veille and Cohen). 1990;162:391-6
The relationship between the umbilical artery systolic/diastolic ratio and umbilical blood gas measurements in specimens obtained by cordocentesis (Weiner). 1990;162:1198-202
Fluid dynamics; *see* **Water-electrolyte balance**
Follicle-stimulating hormone; *see* **FSH**
Follow-up studies
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9
Forceps
A comparison of the morbidity of midforceps and cesarean delivery (Bashore et al). 1990;162:1428-35
Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries (Robertson et al). 1990;162:1436-44
Fragment D-dimer; *see* **Blood coagulation factors**
Free radicals
Studies on cervical intraepithelial neoplasia: the level of octadeca-9,11-dienoic acid and measurement of free radical content by electron spin resonance spectroscopy (Wickens et al). 1990;162:854-8
Fructosamine; *see* **Glucosamine**
Fructose
Serum fructosamine and amniotic fluid insulin levels in patients with gestational diabetes and healthy control subjects (Hofmann et al). 1990;162:1174-7
FSH
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
FSH, animal
The effect of prolactin on murine in vitro fertilization and embryo development (Dodds et al). 1990;162:1553-61

G

Gastroschisis; *see* **Abdominal wall**
GBS-test; *see* ***Streptococcus agalactiae***
Gene expression regulation
Expression of the human inhibin α-subunit gene in preovulatory granulosa-theca cells (Burns et al). 1990;162:273-7
Genetic counseling
Analysis of indications for referral to a multidisciplinary medical genetics clinic: implications for training programs in obstetrics and gynecology (Bombard et al). 1990;162:10-4
Genetic screening
Genetic screening with exfoliated cervicovaginal cells collected by a noninvasive lavage technique performed during routine gynecologic cancer screening (Burk and Spitzer). 1990;162:652-4
Maternal serum Down syndrome screening: unconjugated estriol is not useful (Macri et al). 1990;162:672-3
Maternal serum α-fetoprotein levels in pregnancies among black and white women with fetal open spina bifida: a United States Collaborative Study (Johnson et al). 1990;162:328-31
Maternal serum α-fetoprotein screening for fetal Down syndrome in the United States: results of a survey (Palomaki et al). 1990;162:317-21
Genital diseases, female
Changes in gynecologic cancer staging by the International Federation of Gynecology and Obstetrics. 1990;162:610-1 (Announ.)
Underwear: contamination by human papillomaviruses (Bergeron et al). 1990;162:25-9
Genital diseases, male
Underwear: contamination by human papillomaviruses (Bergeron et al). 1990;162:25-9
Genital neoplasms, female
Predictive value and prevalence (Kürzl) (Letter); (Patsner) (Reply). 1990;162:871-2
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Single-dose antibiotic prophylaxis for patients undergoing extended pelvic surgery for gynecologic malignancy (Orr et al). 1990;162:718-21
Vaginal bleeding and diethylstilbestrol exposure during pregnancy: relationship to genital tract clear cell adenocarcinoma and vaginal adenosis in daughters (Sharp and Cole). 1990;162:994-1001
Genital warts; *see* **Condyloma acuminata**
Gentamicins
Postpartum gentamicin dosing and endometritis (Stoukides and Souney) (Letter); (Briggs et al) (Reply). 1990;162:1132-3
Gestational age
Black premature births, maternal hematocrits, and gestational age data (Sepkowitz) (Letter); (Leberman et al) (Reply). 1990;162:293-5
Conclusions lack support (Goodlin) (Letter); (Mueller-Heubach) (Reply). 1990;162:1627-8
Intrauterine growth and spastic cerebral palsy. I. Associa-

tion with birth weight for gestational age (Blair and Stanley). 1990;162:229-37
A longitudinal study of maternal digoxin-like immunoreactive substances in normotensive pregnancy and pregnancy-induced hypertension (Kerkez et al). 1990;162:783-7
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Umbilical amino acid concentrations in normal and growth-retarded fetuses sampled in utero by cordocentesis (Cetin et al). 1990;162:253-61

Gestational age, animal
Rabbit alveolar β-adrenergic receptors increase with gestational age (Lewis et al). 1990;162:269-72

Gestational diabetes; *see* **Pregnancy in diabetes**

Gestational trophoblastic disease; *see* **Trophoblastic tumor**

Gloves, surgical
Blood exposure in single versus double gloving during pelvic surgery (Cohn and Seifer). 1990;162:715-7

Glucosamine
Fructosamine assay as screening test for gestational diabetes (Kaufman) (Letter); (Comtois and Desjarlais) (Reply). 1990;162:1339-41
Fructosamine in gestational diabetes (Doery et al) (Letter); (Comtois and Desjarlais) (Reply). 1990;162:1635-6

Glucose
Insulin-dependent diabetes mellitus associated with danazol (Seifer et al). 1990;162:474-5
Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14
Studies of hexokinase activity in human and mouse oocyte (Tsutsumi et al). 1990;162:1301-4

Glucose tolerance test
Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14
Serum fructosamine and amniotic fluid insulin levels in patients with gestational diabetes and healthy control subjects (Hofmann et al). 1990;162:1174-7

Glycoprotein hormones, alpha subunit
Orosomucoid in human pregnancy serum diminishes bioavailability of the progesterone antagonist RU 486 in rats (Steingold et al). 1990;162:523-4

Glycospingolipids
Demonstration of Fabry's disease deposits in placenta (Popli et al). 1990;162:464-5

Gonadotropin-releasing hormone; *see* **Pituitary hormone releasing hormone**

Gonadotropins
Cytokine-mediated regulation of ovarian function: tumor necrosis factor α inhibits gonadotropin-supported progesterone accumulation by differentiating and luteinized murine granulosa cells (Adashi et al). 1990;162:889-99
The effect of aging on hypothalamic function in oophorectomized women (Alexander et al). 1990;162:446-9
Ovulation and successful pregnancy in a woman with ovarian failure after hypophysectomy and gonadotropin therapy (Check). 1990;162:775-6

Gonadotropins, chorionic
Feedback mechanism of human chorionic gonadotropin secretion (Dericks-Tan and Taubert). 1990;162:608-9 (Letter)
Prediction of residual trophoblastic tissue in first-trimester abortions and low levels of human chorionic gonadotropin β-subunit (Schiff et al). 1990;162:797-801

Gonococcus*; *see* *Neisseria gonorrhoeae

Granulocytes
Uterine large granular lymphocytes: A possible role in embryonic implantation? (King and Loke). 1990;162:308-10 (Clin. opinion)

Granulosa cells
Cytokine-mediated regulation of ovarian function: tumor necrosis factor α inhibits gonadotropin-supported progesterone accumulation by differentiating and luteinized murine granulosa cells (Adashi et al). 1990;162:889-99
Expression of the human inhibin α-subunit gene in preovulatory granulosa-theca cells (Burns et al). 1990;162:273-7
Induction of class II major histocompatibility complex antigen expression in human granulosa cells by interferon gamma: a potential mechanism contributing to autoimmune ovarian failure (Hill et al). 1990;162:534-40
Spontaneous cell death in the chorion laeve (Parmley). 1990;162:1576-83

Growth
Neonatal growth assessment score: a new approach to the detection of intrauterine growth retardation in the newborn (Deter et al). 1990;162:1030-6

Growth, fetal; *see* **Fetal development**

Growth retardation, intrauterine; *see* **Fetal growth retardation**

Gynecologic diseases; *see* **Genital diseases, female**

Gynecologic examination; *see* **Physical examination**

Gynecologic neoplasms; *see* **Genital neoplasms, female**

Gynecology
Subspecialty of gynecologic oncology proposed to manage breast disease (Kelley). 1990;162:1638 (Letter)

H

HBsAg; *see* **Hepatitis B surface antigens**

Health care expenditures; *see* **Expenditures, health**

Heart arrest
Cardiovascular collapse during laparoscopy (Lip and Delhaas) (Letter); (Brantley) (Reply). 1990;162:873

Heart rate, fetal
Antepartum heart rate patterns in small-for-gestational-age third-trimester fetuses: correlations with blood gas values obtained at cordocentesis (Visser et al). 1990;162:698-703
Assessment of fetal response to exercise in pregnancy (Rafla) (Letter); (Morrow) (Reply). 1990;162:1129-30
Limitations of antenatal fetal heart rate monitors (Dawes et al). 1990;162:170-3
Prophylactic intrapartum amnioinfusion: a randomized clinical trial (Strong et al). 1990;162:1370-5
What is fetal distress? (Parer and Livingston). 1990;162:1421-7

HELLP syndrome; *see* **Pregnancy complications, hematologic**

Helper cells
Immunohistologic evidence that villitis in human normal term placentas is an immunologic lesion (Labarrere et al). 1990;162:515-22

Hemabate; *see* **Prostaglandins F, synthetic**

Hematocrit
Black premature births, maternal hematocrits, and gestational age data (Sepkowitz) (Letter); (Leberman et al) (Reply). 1990;162:293-5

Hematocrit—cont'd
Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4
Need for plasma volume estimation (Goodlin). 1990;162:601 (Letter)
Hematologic diseases
Measured menstrual blood loss in women with a bleeding disorder or using oral anticoagulant therapy (van Eijkeren et al). 1990;162:1261-3
Hematoma
Absence of perineal pain does not rule out puerperal hematoma (Harris) (Letter); (Chin) (Reply). 1990;162:1357-8
Hemodynamics
Fetal hemodynamic and fetoplacental vascular response to exogenous arginine vasopressin (Irion et al). 1990;162:1115-20
Theoretical and technical questions involved with hemodynamic responses (Clapp) (Letter); (Morrow) (Reply). 1990;162:867-8
Hemoglobins
The relationship of maternal erythrocyte oxygen transport parameters to intrauterine growth retardation (Brown et al). 1990;162:223-9
Hemolysis
The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37
Hemolytic disease of newborn; *see* **Erythroblastosis, fetal**
Hemoperitoneum
Pregnancy hemoperitoneum and placenta percreta in a patient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6
Reevaluation of the role of culdocentesis in the management of ectopic pregnancy (Vermesh et al). 1990;162:411-3
Hemorrhage
Chronic, massive fetomaternal hemorrhage treated with repeated fetal intravascular transfusions (Fischer et al). 1990;162:203-4
Intractable venous sacral hemorrhage: use of stainless steel thumbtacks to obtain hemostasis (Patsner and Orr). 1990;162:452
Treatment in an obstetric intensive care unit (Mabie and Sibai). 1990;162:1-4 (Clin. opinion)
Hemorrhage, fetomaternal; *see* **Fetomaternal transfusion**
Hemorrhage, postpartum
Absence of perineal pain does not rule out puerperal hematoma (Harris) (Letter); (Chin) (Reply). 1990;162:1357-8
Controlling refractory atonic postpartum hemorrhage with Hemabate sterile solution (Oleen and Mariano). 1990;162:205-8
Management of severe postpartum hemorrhage by intrauterine irrigation with prostaglandin E_2 (Peyser and Kupferminc). 1990;162:694-6
Volume and timing are key to use of intraumbilical oxytocin for management of retained placenta (Golan). 1990;162:1628-9 (Letter)
Hemostasis
Changes in hemostasis activity during delivery and the immediate postpartum period (Gerbasi et al). 1990;162:1158-63
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Hemostasis, surgical
Intractable venous sacral hemorrhage: use of stainless steel thumbtacks to obtain hemostasis (Patsner and Orr). 1990;162:452
Heparin
Heparin prophylaxis during pregnancy (Brill-Edwards et al) (Letter); (Bergqvist et al) (Reply). 1990;162:870-1
Hepatic vein thrombosis
Postpartum Budd-Chiari syndrome with prolonged hypercoagulability state (Ilan et al). 1990;162:1164-5
Hepatitis B surface antigens
HBsAg in placentas (Lin) (Letter); (Lucifora) (Reply). 1990;162:1361
Herpes genitalis
Does maternal genital herpes infection influence fetal gender? (McGregor and Leff). 1990;162:1346-7 (Letter)
Hexokinase
Studies of hexokinase activity in human and mouse oocyte (Tsutsumi et al). 1990;162:1301-4
Histidyl proline diketopiperazine
The neuropeptide histidyl proline diketopiperazine throughout human pregnancy: an inverse correlation with amniotic fluid prolactin (Wolf et al). 1990;162:740-5
Histocompatibility antigens class II
Induction of class II major histocompatibility complex antigen expression in human granulosa cells by interferon gamma: a potential mechanism contributing to autoimmune ovarian failure (Hill et al). 1990;162:534-40
HIV
Causal effect questioned (Amstey) (Letter); (Carson) (Reply). 1990;162:868
Serious infections during pregnancy among women with advanced human immunodeficiency virus infection (Minkoff et al). 1990;162:30-4
Hormonal contraceptives; *see* **Contraceptives, oral, hormonal**
Hormone antagonists
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
Hospitals, community
Effects of selection bias on outcomes at referral centers (Sepkowitz) (Letter); (Lubchenco) (Reply). 1990;162:1629-31
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43
Hospitals, urban
Use of the labor-delivery-recovery room in an urban tertiary care hospital (Williams and Mervis). 1990;162:23-4
Human chorionic gonadotropin; *see* **Gonadotropins, chorionic**
Human immunodeficiency virus; *see* **HIV**
Human menopausal gonadotropins; *see* **Gonadotropins**
Human papillomaviruses; *see* **Papillomaviruses**

Hybridization
Underwear: contamination by human papillomaviruses (Bergeron et al). 1990;162:25-9
Hydatidiform mole
Diagnostic and therapeutic curettage in gestational trophoblastic disease (Schlaerth et al). 1990;162:1465-71
Gestational trophoblastic disease: What have we learned in the past decade? (Jones). 1990;162:1286-95
Hormonal contraception in the postmolar interval (Yuen and Callegari). 1990;162:1345 (Letter)
Hydramnios
The amniotic fluid index in normal human pregnancy (Moore and Cayle). 1990;162:1168-73
Hydramnios in the third trimester of pregnancy: a change in the distribution of accompanying fetal anomalies as a result of early ultrasonographic prenatal diagnosis (Ben-Chitrit et al). 1990;162:1344-5 (Letter)
Hydramnios in twin pregnancy (Machin and Still). 1990;162:1625-6 (Letter)
Maternal indomethacin therapy in the treatment of polyhydramnios (Mamopoulos et al). 1990;162:1225-9
Treatment of twins with hydramnios (Thorp and Chescheir) (Letter); (Lange and Harman) (Reply). 1990;162:1625-6
Hydrogen-ion concentration
Is pH test paper as accurate as the electronic measurement of the pH of vaginal secretions? (Thomason et al). 1990;162:1213-4
Hydronephrosis
Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention (Crombleholme et al). 1990;162:1239-44
Hydrops fetalis; *see also* **Erythroblastosis, fetal**
Aneurysm of the vein of Galen: a new cause for Ballantyne syndrome (Ordorica et al). 1990;162:1166-7
Intrafetal prostaglandin $F_{2\alpha}$ administration for midtrimester pregnancy termination: a case report (Christodoulou et al). 1990;162:1245-6
Prediction of fetoplacental blood volume in isoimmunized pregnancy (Leduc and Moise) (Letter); (MacGregor) (Reply). 1990;162:1124
Hydrops fetalis, animal
The development of hydrops fetalis in the ovine fetus after lymphatic ligation or lymphatic excision (Andres and Brace). 1990;162:1331-4
Hydroxyeicosatetraenoic acids
Mechanisms of parturition: the transfer of prostaglandin E_2 and 5-hydroxyeicosatetraenoic acid across fetal membranes (Bennett et al). 1990;162:683-7
21-Hydroxylase; *see* **Steroid-21-hydroxylase**
Hypercholesterolemia, familial
Pregnancy in a homozygous familial hypercholesterolemic patient treated with long-term plasma exchange (Beigel et al). 1990;162:77-8
Hypercorticism; *see* **Adrenal gland hyperfunction**
Hyperemesis gravidarum
Hyperemesis gravidarum and fetal growth retardation (Chin). 1990;162:1349 (Letter)
Hyperimmune globulin; *see* **Immunization, passive**
Hypersensitivity
Recurrent allergic vulvovaginitis: treatment with *Candida albicans* allergen immunotherapy (Rigg et al). 1990;162:332-6
Hypertension
A comparison of no medication versus methyldopa or labetalol in chronic hypertension during pregnancy (Sibai et al). 1990;162:960-7
Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7
Labetalol pharmacokinetics in pregnancy-induced hypertension (Rogers et al). 1990;162:362-6
A longitudinal study of maternal digoxin-like immunoreactive substances in normotensive pregnancy and pregnancy-induced hypertension (Kerkez et al). 1990;162:783-7
A longitudinal study of respiratory changes in normal human pregnancy with cross-sectional data on subjects with pregnancy-induced hypertension (Rees et al). 1990;162:826-30
Methodologic queries: clinical significance of mean arterial blood pressure in second trimester (Ales and Druzin) (Letter); (Sibai) (Reply). 1990;162:876-7
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162:1065-6
Proteinuria and outcome of 444 pregnancies complicated by hypertension (Ferrazzani et al). 1990;162:366-71
Treatment in an obstetric intensive care unit (Mabie and Sibai). 1990;162:1-4 (Clin. opinion)
Hypertension, animal
The relationship between experimentally determined litter size and maternal blood pressure in spontaneously hypertensive rats (Ahokas and Sibai). 1990;162:841-7
Hypertension, renal
Acute renal failure in hypertensive disorders of pregnancy (Sibai et al). 1990;162:777-83
Hypertriglyceridemia
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al). 1990;162:382-6
Hypoandrogenism; *see* **Androgens**
Hypoglycemia
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
Hypophysectomy
Ovulation and successful pregnancy in a woman with ovarian failure after hypophysectomy and gonadotropin therapy (Check). 1990;162:775-6
Hypotension
Magnesium plus nifedipine (Ales) (Letter); (Waisman) (Reply). 1990;162:288
Hypothalamus
The effect of aging on hypothalamic function in oophorectomized women (Alexander et al). 1990;162:446-9
Hypovolemic shock; *see* **Shock**
Hypoxemia; *see* **Anoxemia**
Hyskon
Disseminated intravascular coagulopathy and adult respiratory distress syndrome: life-threatening complications of hysteroscopy (Jedeikin et al). 1990;162:44-5
Hysterectomy
The effect of hysterectomy and bilateral oophorectomy in women with severe premenstrual syndrome (Casper and Hearn). 1990;162:105-9
Hysterectomy: a medical-legal perspective, 1975 to 1985 (Whitelaw). 1990;162:1451-8
Leiomyosarcoma in a series of hysterectomies performed for presumed uterine leiomyomas (Leibsohn et al). 1990;162:968-76

Hysterectomy—cont'd
Single-dose antibiotic prophylaxis for patients undergoing extended pelvic surgery for gynecologic malignancy (Orr et al). 1990;162:718-21
Hysterectomy, vaginal
A new method for gaining entry into the scarred anterior cul-de-sac during transvaginal hysterectomy (Hoffman and Jaeger). 1990;162:1269-70
Sacrospinous ligament fixation at the time of transvaginal hysterectomy (Cruikshank and Cox). 1990;162:1611-9
Hysterosalpingography
Evaluation of hysteroscopic management of the septate uterus (Simpson). 1990;162:598-9 (Letter)
Hysteroscopy; *see* **Uterus, analysis**

I

Ibuprofen
Oligohydramnios in each sac of a triplet gestation caused by Motrin—fulfilling Kock's postulates (Wiggins and Elliott). 1990;162:460-1
Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10
IgG
Increasing quantity of maternal immunoglobulin G in trophoblastic tissue before the onset of normal labor (Akin et al). 1990;162:1154-7
IgM
Natural immunoglobulin M antibodies against *Toxoplasma gondii* during pregnancy (Gussetti et al) (Letter); (Konishi) (Reply). 1990;162:1359-60
Image processing, computer-assisted
The computerized digital imaging colposcope: future directions (Crisp et al). 1990;162:1491-8
Immunity, cellular
Interferon gamma and depressed cellular immune response (Fuith et al). 1990;162:1338 (Letter)
Immunization, passive
Resolution of severe thrombocytopenia in a pregnant patient with rhesus-negative blood with autoimmune thrombocytopenic purpura after intravenous rhesus immune globulin (Moise et al). 1990;162:1237-8
Immunoenzyme techniques
CA 125 is released by human amnion cells in culture (Barbati et al). 1990;162:266-8
Immunohistochemistry
Immunohistochemical localization of epidermal growth factor receptor during implantation in the rabbit (Hofmann and Anderson). 1990;162:837-41
Immunologic lesion; *see* **Antibody formation**
Immunoperoxidase techniques; *see* **Immunoenzyme techniques**
Immunotherapy
Recurrent allergic vulvovaginitis: treatment with *Candida albicans* allergen immunotherapy (Rigg et al). 1990;162:332-6
Implantation; *see* **Ovum implantation**
In vitro fertilization; *see* **Fertilization in vitro**
Incontinence, urinary; *see* **Urinary incontinence**
Indigent care; *see* **Medical indigency**
Indomethacin
The effect of indomethacin on the pulsatility index of the umbilical artery in human fetuses (Moise et al). 1990;162:199-202
Maternal indomethacin therapy in the treatment of polyhydramnios (Mamopoulos et al). 1990;162:1225-9
Placental transfer of indomethacin in the human pregnancy (Moise et al). 1990;162:549-54
Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes (Novy et al). 1990;162:1412-20
Transplacental cardiovascular effects of four popular analgesics in rats (Momma and Takao). 1990;162:1304-10
Infant, low birth weight
Chlamydia trachomatis infection in pregnancy and effect of treatment on outcome (Ryan et al). 1990;162:34-9
Intrauterine growth retardation and preterm delivery: prenatal risk factors in an indigent population (Wen et al). 1990;162:213-8
A model for the prospective analysis of perinatal deaths in a perinatal network (Moawad et al). 1990;162:15-22
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Strategies for the prevention of low birth weight (Kliegman et al). 1990;162:1073-83 (Curr. dev.)
Infant, newborn
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
Neonatal growth assessment score: a new approach to the detection of intrauterine growth retardation in the newborn (Deter et al). 1990;162:1030-6
Infant, premature
Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9
An analysis of antenatal tests to detect infection in preterm premature rupture of the membranes (Ohlsson and Wang). 1990;162:809-18 (Curr. dev.)
The association of fetal and newborn metabolic acidosis with severe periventricular leukomalacia in the preterm newborn (Low et al). 1990;162:977-82
Black premature births, maternal hematocrits, and gestational age data (Sepkowitz) (Letter); (Leberman et al) (Reply). 1990;162:293-5
Conclusions lack support (Goodlin) (Letter); (Mueller-Heubach) (Reply). 1990;162:1627-8
Effects of birth weight and sociodemographic variables on mental development of neonatal intensive care unit survivors (Resnick et al). 1990;162:374-8
Intrapartum asphyxia in the preterm fetus <2000 gm (Low et al). 1990;162:378-82
Intrauterine growth retardation and preterm delivery: prenatal risk factors in an indigent population (Wen et al). 1990;162:213-8
Prediction of preterm delivery: Is it substantially improved by routine vaginal examinations? (Blondel et al). 1990;162:1042-8
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Strategies for the prevention of low birth weight (Kliegman et al). 1990;162:1073-83 (Curr. dev.)
Study of preterm birth draws different interpretation (Goldenberg et al). 1990;162:1626-7 (Letter)
Infant, small for gestational age
Antepartum heart rate patterns in small-for-gestational-age third-trimester fetuses: correlations with blood gas values obtained at cordocentesis (Visser et al). 1990;162:698-703
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al). 1990;162:382-6

Intrauterine growth retardation is not the same as small for gestational age (Goodlin) (Letter); (Goldenberg et al) (Reply). 1990;162:1642-3
Middle cerebral artery blood flow in normal and growth-retarded fetuses (Veille and Cohen). 1990;162:391-6
Relation of rate of urine production to oxygen tension in small-for-gestational-age fetuses (Nicolaides et al). 1990;162:387-91
Umbilical amino acid concentrations in normal and growth-retarded fetuses sampled in utero by cordocentesis (Cetin et al). 1990;162:253-61

Infant care
A model for the prospective analysis of perinatal deaths in a perinatal network (Moawad et al). 1990;162:15-22

Infant mortality
The abnormal fetal biophysical profile score. V. Predictive accuracy according to score composition (Manning et al). 1990;162:918-27
Effects of selection bias on outcomes at referral centers (Sepkowitz) (Letter); (Lubchenco) (Reply). 1990;162:1629-31
Fetal assessment based on fetal biophysical profile scoring. III. Positive predictive accuracy of the very abnormal test (biophysical profile score = 0) (Manning et al). 1990;162:398-402
Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality (Manning et al). 1990;162:703-9
A model for the prospective analysis of perinatal deaths in a perinatal network (Moawad et al). 1990;162:15-22
Strategies for the prevention of low birth weight (Kliegman et al). 1990;162:1073-83 (Curr. dev.)
Study of preterm birth draws different interpretation (Goldenberg et al). 1990;162:1626-7 (Letter)

Infection
Blood exposure in single versus double gloving during pelvic surgery (Cohn and Seifer). 1990;162:715-7
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43

Infection, puerperal; *see* **Puerperal infection**

Infertility, female
Contractions of the inner third of the myometrium (de Vries et al). 1990;162:679-82
The impact of luteal phase inadequacy in an infertile population (Wentz et al). 1990;162:937-45
Nafarelin in the treatment of infertility caused by endometriosis (Barlow). 1990;162:576-9 (Symposium)
Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting (DiMarzo et al). 1990;162:1483-90
Treatment-dependent and treatment-independent pregnancy among women with periadnexal adhesions (Tulandi et al). 1990;162:354-7
Uterine rupture after treatment of Asherman's syndrome (Hulka) (Letter); (Deaton et al) (Reply). 1990;162:1352-3
The validity of the postcoital test (Griffith and Grimes). 1990;162:615-20 (Clin. opinion)

Infertility, male
Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting (DiMarzo et al). 1990;162:1483-90

Informed consent
Clinical guides to preventing ethical conflicts between pregnant women and their physicians (Chervenak and McCullough). 1990;162:303-7 (Clin. opinion)
Vaginal birth after cesarean or repeat cesarean section: Medical risks or social realities? (Kirk et al). 1990;162:1398-405

Infusion pumps
A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9

Infusions, intravenous
Transient oligohydramnios in a severely hypovolemic gravid woman at 35 weeks' gestation, with fluid reaccumulating immediately after intravenous maternal hydration (Sherer et al). 1990;162:770-1

Infusions, parenteral
Amniotic fluid volume increase after amnioinfusion of a fixed volume (Strong et al). 1990;162:746-8
Intrauterine transfusion—intraperitoneal versus intravascular approach: a case-control comparison (Harman et al). 1990;162:1053-9

Inhibin
Expression of the human inhibin α-subunit gene in preovulatory granulosa-theca cells (Burns et al). 1990;162:273-7

Insemination, artificial
Luteinizing hormone and ovulation timing (Cline). 1990;162:1341 (Letter)
Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting (DiMarzo et al). 1990;162:1483-90

Insulin
Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14
Serum fructosamine and amniotic fluid insulin levels in patients with gestational diabetes and healthy control subjects (Hofmann et al). 1990;162:1174-7

Insulin-dependent diabetes mellitus; *see* **Diabetes mellitus, insulin-dependent**

Intensive care units
Treatment in an obstetric intensive care unit (Mabie and Sibai). 1990;162:1-4 (Clin. opinion)

Intensive care units, neonatal
Effects of birth weight and sociodemographic variables on mental development of neonatal intensive care unit survivors (Resnick et al). 1990;162:374-8

Interferon alfa-2b
Intralesional interferon alfa-2b for the treatment of genital warts (Welander et al). 1990;162:348-54

Interferon gamma, recombinant
Induction of class II major histocompatibility complex antigen expression in human granulosa cells by interferon gamma: a potential mechanism contributing to autoimmune ovarian failure (Hill et al). 1990;162:534-40

Interferon type II
Interferon gamma and depressed cellular immune response (Fuith et al). 1990;162:1338 (Letter)

International Federation of Gynecology and Obstetrics
Changes in gynecologic cancer staging by the International Federation of Gynecology and Obstetrics. 1990;162:610-1 (Announ.)

Internship and residency
Analysis of indications for referral to a multidisciplinary medical genetics clinic: implications for training programs in obstetrics and gynecology (Bombard et al). 1990;162:10-4
Journal article appraisal (Capecchi). 1990;162:1121 (Letter)
Interperitoneal infusions; *see* **Infusions, parenteral**
Interphase
Flow cytometric evaluation of epithelial ovarian cancer (Barnabei et al). 1990;162:1584-92
Intracerebellar hemorrhage; *see* **Cerebral hemorrhage**
Intrauterine growth retardation; *see* **Fetal growth retardation**
Intrauterine transfusion; *see* **Blood transfusion, intrauterine**
Intravenous hydration; *see* **Infusions, intravenous**
Intravenous infusions; *see* **Infusions, intravenous**
Ion channels
Some electrical properties of human pregnant myometrium (Inoue et al). 1990;162:1090-8
Iron
Placental deposits of stainable iron (Knisely) (Letter); (Birkenfeld et al) (Reply). 1990;162:1638-9
Isoimmunization, Rh; *see* **Rh isoimmunization**
Isometric contraction, animal
Effects of hypoxemia with and without acidemia on the isometric contraction time and the electromechanical delay of the fetal myocardium: an experimental study on the ovine fetus (Fouron et al). 1990;162:262-6
Items
Items. 1990;162:302, 612, 878, 1134, 1364, 1670

K

Karyotyping
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Cordocentesis for rapid karyotyping (Shah et al). 1990;162:1548-53
Ketosis
Accelerated starvation in late pregnancy: a comparison between obese women with and without gestational diabetes mellitus (Buchanan et al). 1990;162:1015-20
Kidney failure, acute
Acute renal failure in hypertensive disorders of pregnancy (Sibai et al). 1990;162:777-83
Killer cells, natural
Uterine large granular lymphocytes: A possible role in embryonic implantation? (King and Loke). 1990;162:308-10 (Clin. opinion)
Kraurosis vulvae
Lichen sclerosus, invasive squamous cell carcinoma, and human papillomavirus (Neill et al). 1990;162:1633-4 (Letter)

L

Labetalol
A comparison of no medication versus methyldopa or labetalol in chronic hypertension during pregnancy (Sibai et al). 1990;162:960-7
Labetalol pharmacokinetics in pregnancy-induced hypertension (Rogers et al). 1990;162:362-6
Labor
Active management of labor (Lynch) (Letter); (Leveno et al) (Reply). 1990;162:1637-8
Fetal acoustic stimulation in the early intrapartum period as a predictor of subsequent fetal condition (Sarno et al). 1990;162:762-7
Increasing quantity of maternal immunoglobulin G in trophoblastic tissue before the onset of normal labor (Akin et al). 1990;162:1154-7
Mechanisms of parturition: the transfer of prostaglandin E_2 and 5-hydroxyeicosatetraenoic acid across fetal membranes (Bennett et al). 1990;162:683-7
Labor, induced
The effect of disopyramide on uterine contractions during pregnancy (Tadmor et al). 1990;162:482-6
Myometrial activity after local application of prostaglandin E_2 for cervical ripening and term labor induction (Granström et al). 1990;162:691-4
A nested case-control study of oxytocin and sudden infant death syndrome (Kraus and Bulterys). 1990;162:604-5 (Letter)
Labor, premature; *see also* **Infant, premature**
Activation of the renin-angiotensin system during ritodrine treatment in preterm labor (Hanssens et al). 1990;162:1048-53
Black premature births, maternal hematocrits, and gestational age data (Sepkowitz) (Letter); (Leberman et al) (Reply). 1990;162:293-5
Detection of platelet-activating factor in amniotic fluid of complicated pregnancies (Hoffman et al). 1990;162:525-8
Early signs and symptoms of preterm labor (Katz et al). 1990;162:1150-3
Hydramnios in twin pregnancy (Machin and Still). 1990;162:1625-6 (Letter)
Increasing quantity of maternal immunoglobulin G in trophoblastic tissue before the onset of normal labor (Akin et al). 1990;162:1154-7
Magnesium tocolysis: serum levels versus success (Madden et al). 1990;162:1177-80
Pharmacokinetics and pharmacodynamics of ritodrine after intramuscular administration to pregnant women (Caritis et al). 1990;162:1215-9
Pharmacokinetics of ritodrine administered intravenously: recommendations for changes in the current regimen (Caritis et al). 1990;162:429-37
Placental transfer of indomethacin in the human pregnancy (Moise et al). 1990;162:549-54
The prevalence of substance abuse in patients with suspected preterm labor (Ney et al). 1990;162:1562-7
Production of prostaglandin E_2 by human amnion in vitro in response to addition of media conditioned by microorganisms associated with chorioamnionitis and preterm labor (Lamont et al). 1990;162:819-25
Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance (Lorenz et al). 1990;162:1603-10
Seventy-one quadruplet pregnancies: management and outcome (Collins and Bleyl). 1990;162:1384-92
Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes (Novy et al). 1990;162:1412-20
Symptoms that precede preterm labor and preterm premature rupture of the membranes (Iams et al). 1990;162:486-90
Warning symptoms, uterine contractions, and cervical examination findings in women at risk of preterm delivery (Copper et al). 1990;162:748-54
Labor-delivery-recovery room; *see* **Delivery rooms**

Labor stage, third
Volume and timing are key to use of intraumbilical oxytocin for management of retained placenta (Golan). 1990;162:1628-9 (Letter)
Laparoscopy; *see* Peritoneoscopy
Laparotomy
Cesarean salpingectomy rare but not first (Pelosi). 1990;162:605-6 (Letter)
Leiomyoma
Leiomyosarcoma in a series of hysterectomies performed for presumed uterine leiomyomas (Leibsohn et al). 1990;162:968-76
Leiomyosarcoma
Leiomyosarcoma in a series of hysterectomies performed for presumed uterine leiomyomas (Leibsohn et al). 1990;162:968-76
Vulvar leiomyosarcoma in pregnancy (Kuller et al). 1990;162:164-6
Letters
Letters. 1990;162:288-98, 596-609, 865-77, 1121-33, 1138-63, 1625-44
Leukomalacia, periventricular
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
The association of fetal and newborn metabolic acidosis with severe periventricular leukomalacia in the preterm newborn (Low et al). 1990;162:977-82
Leuprolide acetate
Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy (Barbieri). 1990;162:593-5 (Symposium)
LH
Luteinizing hormone and ovulation timing (Cline). 1990;162:1341 (Letter)
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
LH, animal
The effect of prolactin on murine in vitro fertilization and embryo development (Dodds et al). 1990;162:1553-61
Lichen sclerosis of vulva; *see* Kraurosis vulvae
Lidocaine
Pregnancy does not alter lidocaine toxicity (Morishima et al). 1990;162:1320-4
Ligament fixation; *see* Ligaments, surgery
Ligaments, surgery
Autotransfusion during cesarean section (Zichella and Gramolini). 1990;162:295 (Letter)
Sacrospinous ligament fixation at the time of transvaginal hysterectomy (Cruikshank and Cox). 1990;162:1611-9
Linkage
Demonstration of Fabry's disease deposits in placenta (Popli et al). 1990;162:464-5
Lipids
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)
Effects of nafarelin versus danazol on lipids and calcium metabolism (Bergquist). 1990;162:589-91 (Symposium)
Lithotomy position, adverse effects; *see* Postoperative complications
Litigation frequency; *see* Risk management
Litter size
The relationship between experimentally determined litter size and maternal blood pressure in spontaneously hypertensive rats (Ahokas and Sibai). 1990;162:841-7
Longitudinal studies
A longitudinal study of maternal digoxin-like immunoreactive substances in normotensive pregnancy and pregnancy-induced hypertension (Kerkez et al). 1990;162:783-7
A longitudinal study of respiratory changes in normal human pregnancy with cross-sectional data on subjects with pregnancy-induced hypertension (Rees et al). 1990;162:826-30
Low birth weight; *see* Infant, low birth weight
Lumbosacral region, abnormalities
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Lung, animal
Rabbit alveolar β-adrenergic receptors increase with gestational age (Lewis et al). 1990;162:269-72
Luteal phase
The impact of luteal phase inadequacy in an infertile population (Wentz et al). 1990;162:937-45
Luteinizing hormone; *see* LH
Lymph node excision
The development of hydrops fetalis in the ovine fetus after lymphatic ligation or lymphatic excision (Andres and Brace). 1990;162:1331-4
Lymphatic system, surgery, animal
The development of hydrops fetalis in the ovine fetus after lymphatic ligation or lymphatic excision (Andres and Brace). 1990;162:1331-4
Lymphocytes
Uterine large granular lymphocytes: A possible role in embryonic implantation? (King and Loke). 1990;162:308-10 (Clin. opinion)

M

Macrophages
Cytokine-mediated regulation of ovarian function: tumor necrosis factor α inhibits gonadotropin-supported progesterone accumulation by differentiating and luteinized murine granulosa cells (Adashi et al). 1990;162:889-99
Immunohistologic evidence that villitis in human normal term placentas is an immunologic lesion (Labarrere et al). 1990;162:515-22
Macrosomia; *see* Fetal macrosomia
Magnesium sulfate
Magnesium plus nifedipine (Ales) (Letter); (Waisman) (Reply). 1990;162:288
Magnesium sulfate is the ideal anticonvulsant in preeclampsia-eclampsia (Sibai). 1990;162:1141-5 (Clin. opinion)
Magnesium tocolysis: serum levels versus success (Madden et al). 1990;162:1177-80
Magnetic resonance imaging
Prenatal diagnosis of valvar aortic stenosis by Doppler echocardiography and magnetic resonance imaging (Hata et al). 1990;162:1068-70
Magnetic resonance spectroscopy; *see* Nuclear magnetic resonance
Malpractice
Hysterectomy: a medical-legal perspective, 1975 to 1985 (Whitelaw). 1990;162:1451-8
The placenta in the litigation process (Benirschke). 1990;162:1445-50

Mammography
Breast cancer detection: experience in a suburban community (Goodno). 1990;162:1393-7
Surgical management of breast disease in an obstetrics and gynecology group (Hall et al). 1990;162:1526-34
Mass screening
Maternal serum α-fetoprotein screening for fetal Down syndrome in the United States: results of a survey (Palomaki et al). 1990;162:317-21
Maternal age
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Maternal mortality
Ectopic pregnancy concurrent with induced abortion: incidence and mortality (Atrash et al). 1990;162:726-30
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9
Meconium
Significance of observing no fluid at amniotomy (Druzin and Adams). 1990;162:1006-7
Medical indigency
Intrauterine growth retardation and preterm delivery: prenatal risk factors in an indigent population (Wen et al). 1990;162:213-8
Medical oncology
Subspecialty of gynecologic oncology proposed to manage breast disease (Kelley). 1990;162:1638 (Letter)
Medroxyprogesterone
Designing a schedule of progestin administration in the control of endometrial carcinoma growth in the nude mouse model (Mortel et al). 1990;162:928-36
Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy (Barbieri). 1990;162:593-5 (Symposium)
Melanoma
Primary cervical melanoma (Divers) (Letter); (Sloan) (Reply). 1990;162:293
Menopause
The effect of aging on hypothalamic function in oophorectomized women (Alexander et al). 1990;162:446-9
Evaluation of a continuous combined low-dose regimen of estrogen-progestin for treatment of the menopausal patient (Weinstein et al). 1990;162:1534-42
A study of combined continuous ethinyl estradiol and norethindrone acetate for postmenopausal hormone replacement (Williams et al). 1990;162:438-46
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
Menorrhagia
Hysteroscopy and laparoscopy in women with menorrhagia (Fraser). 1990;162:1264-9
Measured menstrual blood loss in women with a bleeding disorder or using oral anticoagulant therapy (van Eijkeren et al). 1990;162:1261-3
Menstrual cycle
Effect of the menstrual cycle on detection and typing of human papillomavirus in uterine cervical cells (McNicol et al). 1990;162:1037-41
Endometrial involution (Ritter and Philippe) (Letter); (Check) (Reply). 1990;162:1360-1
Transcapillary fluid dynamics during ovarian stimulation for in vitro fertilization (Tollan et al). 1990;162:554-8
Menstruation
Etiology and epidemiology of endometriosis (Barbieri). 1990;162:565-7 (Symposium)
Menstruation disorders
Measured menstrual blood loss in women with a bleeding disorder or using oral anticoagulant therapy (van Eijkeren et al). 1990;162:1261-3
Mental development; *see* **Child development**
Mepivacaine
Pregnancy does not alter lidocaine toxicity (Morishima et al). 1990;162:1320-4
Mesenteric arteries
Characterization of norepinephrine sensitivity in the maternal splanchnic circulation during pregnancy (Crandall et al). 1990;162:1296-301
Mesocolon
Clear cell carcinoma of the sigmoid mesocolon: a tumor of the secondary müllerian system (Evans et al). 1990;162:161-3
Mesonephroma
A 62-year-old woman with endodermal sinus tumor of the ovary (Kinoshita). 1990;162:760-2
Meta-analysis
Is obstetric progress dependent on rigorous randomized controlled trials? (Goodlin) (Letter); (Ohlsson) (Reply). 1990;162:1353-5
Maternal spermicide use and adverse reproductive outcome: a meta-analysis (Einarson et al). 1990;162:655-60
Methotrexate
Reproductive performance after methotrexate treatment of ectopic pregnancy (Stovall et al). 1990;162:1620-4
Methyldopa
A comparison of no medication versus methyldopa or labetalol in chronic hypertension during pregnancy (Sibai et al). 1990;162:960-7
Microcephaly
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
Microinvasion; *see* **Neoplasm metastasis**
Mifepristone; *see* **RU-486**
Mitochondria, muscle
Mitochondrial myopathy and preeclampsia associated with pregnancy (Berkowitz et al). 1990;162:146-7
Monoclonal antibodies; *see* **Antibodies, monoclonal**
Monosomy
Screening of seven putative 45,X subjects with deoxyribonucleic acid probes to detect low-level mosaicism for Y cell lines (Tho et al). 1990;162:59-60
Morbidity
The abnormal fetal biophysical profile score. V. Predictive accuracy according to score composition (Manning et al). 1990;162:918-27
A comparison of the morbidity of midforceps and cesarean delivery (Bashore et al). 1990;162:1428-35
Ectopic pregnancy concurrent with induced abortion: incidence and mortality (Atrash et al). 1990;162:726-30
Fetal assessment based on fetal biophysical profile scoring. III. Positive predictive accuracy of the very abnormal test (biophysical profile score = 0) (Manning et al). 1990;162:398-402

Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality (Manning et al). 1990;162:703-9
The Green Bay cesarean section study. I. The physician factor as a determinant of cesarean birth rates (DeMott and Sandmire). 1990;162:1593-602
Predicting neonatal morbidity after perinatal asphyxia: a scoring system (Portman et al). 1990;162:174-82

Mortality; *see also* Fetal death; Infant mortality; Maternal mortality
Fatal pulmonary embolism during legal induced abortion in the United States from 1972 to 1985 (Lawson et al). 1990;162:986-90

Mosaicism
Cytogenetic results of chorionic villus sampling: high success rate and diagnostic accuracy in the United States collaborative study (Ledbetter et al). 1990;162:495-501 (Curr. invest.)
Screening of seven putative 45,X subjects with deoxyribonucleic acid probes to detect low-level mosaicism for Y cell lines (Tho et al). 1990;162:59-60

Motrin; *see* Ibuprofen

Müllerian ducts
Clear cell carcinoma of the sigmoid mesocolon: a tumor of the secondary müllerian system (Evans et al). 1990;162:161-3

Multicenter studies
Nafarelin versus danazol in the treatment of endometriosis (Rolland and van der Heijden). 1990;162:586-8 (Symposium)

Multiple gestation; *see* Pregnancy, multiple

Muscle, smooth
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8

Myocardium, animal
Effects of hypoxemia with and without acidemia on the isometric contraction time and the electromechanical delay of the fetal myocardium: an experimental study on the ovine fetus (Fouron et al). 1990;162:262-6

Myoma
Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy (Barbieri). 1990;162:593-5 (Symposium)

Myometrium
Contractions of the inner third of the myometrium (de Vries et al). 1990;162:679-82
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8
Myomectomy as a reproductive procedure (Smith and Uhlir). 1990;162:1476-82
Myometrial activity after local application of prostaglandin E_2 for cervical ripening and term labor induction (Granström et al). 1990;162:691-4
Some electrical properties of human pregnant myometrium (Inoue et al). 1990;162:1090-8

Myometrium, animal
α_2-Adrenergic receptors in guinea pig myometrium in late pregnancy: evidence for a predominantly postjunctional location (Arkinstall et al). 1990;162:831-6

Myosin
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8

Myosin-light-chain kinase
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8

N

Nafarelin
Comparison of the pharmacology of nafarelin and danazol (Barbieri). 1990;162:581-5 (Symposium)
Effects of nafarelin on bone density (Jacobson). 1990;162:591-2 (Symposium)
Effects of nafarelin versus danazol on lipids and calcium metabolism (Bergquist). 1990;162:589-91 (Symposium)
Efficacy and safety of nafarelin in the treatment of endometriosis (Henzl and Kwei). 1990;162:570-4 (Symposium)
Gonadotropin-releasing hormone analogs in the treatment of endometriomas (Schenken). 1990;162:579-81 (Symposium)
Nafarelin in the treatment of infertility caused by endometriosis (Barlow). 1990;162:576-9 (Symposium)
Nafarelin in the treatment of pelvic pain caused by endometriosis (Shaw). 1990;162:574-6 (Symposium)
Nafarelin versus danazol in the treatment of endometriosis (Rolland and van der Heijden). 1990;162:586-8 (Symposium)

Natriuretic hormone
Increase in the plasma levels of the N-terminal and C-terminal portions of the prohormone of atrial natriuretic factor during normal pregnancy (Merkouris et al). 1990;162:359-64

Natriuretic peptides, atrial
Birth stress increases fetal atrial natriuretic factor (Andersson et al) (Letter); (Cheung and Brace) (Reply). 1990;162:372-3
Increase in the plasma levels of the N-terminal and C-terminal portions of the prohormone of atrial natriuretic factor during normal pregnancy (Merkouris et al). 1990;162:359-64
Plasma atrial natriuretic factor and urinary excretion of a ouabain displacing factor and dopamine in normotensive pregnant women before and after delivery (Gregoire et al). 1990;162:71-6

Natural killer cells; *see* Killer cells, natural

Neisseria gonorrhoeae
Oral contraceptives and infection rates (Grimes and Mishell) (Letter); (Louv et al) (Reply). 1990;162:1121-2

Neonatal intensive care units; *see* Intensive care units, neonatal

Neoplasm metastasis
Lichen sclerosus, invasive squamous cell carcinoma, and human papillomavirus (Neill et al). 1990;162:1633-4 (Letter)
Stage IA_2 squamous carcinoma of the cervix: difficult diagnosis and therapeutic dilemma (Greer et al). 1990;162:1406-11

Neoplasm staging
Changes in gynecologic cancer staging by the International Federation of Gynecology and Obstetrics. 1990;162:610-1 (Announ.)
Stage IA_2 squamous carcinoma of the cervix: difficult diagnosis and therapeutic dilemma (Greer et al). 1990;162:1406-11

Neural tube defects
First-trimester diagnosis of exencephaly (Kennedy et al). 1990;162:461-3

Neurologic examination
Severe acidosis and subsequent neurologic status (Fee et al). 1990;162:802-6
Neuropeptides
The neuropeptide histidyl proline diketopiperazine throughout human pregnancy: an inverse correlation with amniotic fluid prolactin (Wolf et al). 1990;162: 740-5
Newborn infant; *see* Infant, newborn
Nifedipine
Magnesium plus nifedipine (Ales) (Letter); (Waisman) (Reply). 1990;162:288
The use of nifedipine during the postpartum period in patients with severe preeclampsia (Barton et al). 1990;162:788-92
NK cells; *see* Killer cells, natural
Norepinephrine
Characterization of norepinephrine sensitivity in the maternal splanchnic circulation during pregnancy (Crandall et al). 1990;162:1296-301
Norethindrone
Effects of nafarelin on bone density (Jacobson). 1990;162:591-2 (Symposium)
A study of combined continuous ethinyl estradiol and norethindrone acetate for postmenopausal hormone replacement (Williams et al). 1990;162:438-46
Norgestrel
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103
Nuclear magnetic resonance
Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—preliminary data (Raman et al). 1990;162:1511-7
Nutrition
Prepregnancy weight status, prenatal weight gain, and the outcome of term twin gestations (Brown and Schloesser). 1990;162:182-6

O

Obesity
Accelerated starvation in late pregnancy: a comparison between obese women with and without gestational diabetes mellitus (Buchanan et al). 1990;162:1015-20
Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14
Macrosomia: influence of maternal overweight among a low-income population (Larsen et al). 1990;162:490-4
Obstetrician-gynecologist; *see* Specialties, medical
Obstructive uropathy; *see* Hydronephrosis
Octadeca-9,11-dienoic acid
Studies on cervical intraepithelial neoplasia: the level of octadeca-9,11-dienoic acid and measurement of free radical content by electron spin resonance spectroscopy (Wickens et al). 1990;162:854-8
Oligohydramnios; *see* Amniotic fluid
Omentum
Cesarean salpingectomy rare but not first (Pelosi). 1990;162:605-6 (Letter)
Oncogenes
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103
Oncology; *see* Medical oncology
Oocytes
Placental production of estradiol and progesterone after oocyte donation in patients with primary ovarian failure (Devroey et al). 1990;162:66-70
Studies of hexokinase activity in human and mouse oocyte (Tsutsumi et al). 1990;162:1301-4
Oocytes, animal
The effect of prolactin on murine in vitro fertilization and embryo development (Dodds et al). 1990;162:1553-61
Studies of hexokinase activity in human and mouse oocyte (Tsutsumi et al). 1990;162:1301-4
Oophorectomy; *see* Ovariectomy
Oophoritis
Induction of class II major histocompatibility complex antigen expression in human granulosa cells by interferon gamma: a potential mechanism contributing to autoimmune ovarian failure (Hill et al). 1990;162:534-40
Opportunistic infections
Serious infections during pregnancy among women with advanced human immunodeficiency virus infection (Minkoff et al). 1990;162:30-4
Oral contraceptives; *see* Contraceptives, oral
Orosomucoid
Orosomucoid in human pregnancy serum diminishes bioavailability of the progesterone antagonist RU 486 in rats (Steingold et al). 1990;162:523-4
Osteoporosis
Effects of nafarelin on bone density (Jacobson). 1990;162:591-2 (Symposium)
A study of combined continuous ethinyl estradiol and norethindrone acetate for postmenopausal hormone replacement (Williams et al). 1990;162:438-46
Ouabain
Plasma atrial natriuretic factor and urinary excretion of a ouabain displacing factor and dopamine in normotensive pregnant women before and after delivery (Gregoire et al). 1990;162:71-6
Ovarian cycle; *see* Menstrual cycle
Ovarian cysts
Gonadotropin-releasing hormone analogs in the treatment of endometriomas (Schenken). 1990;162:579-81 (Symposium)
Ovarian diseases
Hormone activity and autoimmune function (Pun and Ho) (Letter); (Gleicher and El-Roeiy) (Reply). 1990;162: 866-7
Induction of class II major histocompatibility complex antigen expression in human granulosa cells by interferon gamma: a potential mechanism contributing to autoimmune ovarian failure (Hill et al). 1990;162:534-40
Ovulation and successful pregnancy in a woman with ovarian failure after hypophysectomy and gonadotropin therapy (Check). 1990;162:775-6
Pregnancy hemoperitoneum and placenta percreta in a patient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6
Premature ovarian failure (Nelson and Merriam) (Letter); (Check) (Reply). 1990;162:874-6
Treatment-dependent and treatment-independent pregnancy among women with periadnexal adhesions (Tulandi et al). 1990;162:354-7

Ovarian function tests
Cytokine-mediated regulation of ovarian function: tumor necrosis factor α inhibits gonadotropin-supported progesterone accumulation by differentiating and luteinized murine granulosa cells (Adashi et al). 1990;162:889-99
Ovarian neoplasms
Bilateral ovarian neoplasms and the risk of malignancy (Koonings et al). 1990;162:167-9
Coexistence of mucinous cystadenoma of the ovary and ovarian sarcoidosis (White et al). 1990;162:1284-5
Flow cytometric evaluation of epithelial ovarian cancer (Barnabei et al). 1990;162:1584-92
Heterogeneity of antigen expression in advanced epithelial ovarian cancer (Berchuck et al). 1990;162:883-8
A 62-year-old woman with endodermal sinus tumor of the ovary (Kinoshita). 1990;162:760-2
Ovarian stimulation; *see* **Estrogens**
Ovariectomy
The effect of aging on hypothalamic function in oophorectomized women (Alexander et al). 1990;162:446-9
The effect of hysterectomy and bilateral oophorectomy in women with severe premenstrual syndrome (Casper and Hearn). 1990;162:105-9
Lasting response to ovariectomy in severe intractable premenstrual syndrome (Casson et al). 1990;162:99-105
Pelviscopic adnexectomy (Perry and Upchurch). 1990;162:79-81
Ovary
Placental production of estradiol and progesterone after oocyte donation in patients with primary ovarian failure (Devroey et al). 1990;162:66-70
Ovulation
Luteinizing hormone and ovulation timing (Cline). 1990;162:1341 (Letter)
Ovulation and successful pregnancy in a woman with ovarian failure after hypophysectomy and gonadotropin therapy (Check). 1990;162:775-6
Ovulation induction
Selective termination: clinical experience and residual risks (Evans et al). 1990;162:1568-75
Ovulation induction, animal
The effect of prolactin on murine in vitro fertilization and embryo development (Dodds et al). 1990;162:1553-61
Ovum implantation
Uterine large granular lymphocytes: A possible role in embryonic implantation? (King and Loke). 1990;162:308-10 (Clin. opinion)
Ovum implantation, animal
Immunohistochemical localization of epidermal growth factor receptor during implantation in the rabbit (Hofmann and Anderson). 1990;162:837-41
Oxygen
The relationship of maternal erythrocyte oxygen transport parameters to intrauterine growth retardation (Brown et al). 1990;162:223-9
Oxytocin
A nested case-control study of oxytocin and sudden infant death syndrome (Kraus and Bulterys). 1990;162:604-5 (Letter)
Umbilical vein oxytocin (Goodlin) (Letter); (Carey and Reddy) (Reply). 1990;162:1125-6
Volume and timing are key to use of intraumbilical oxytocin for management of retained placenta (Golan). 1990;162:1628-9 (Letter)

P

Pacific Coast Obstetrical and Gynecological Society
Transactions of the fifty-sixth annual meeting of the Pacific Coast Obstetrical and Gynecological Society. 1990;162:1365-498
Papillomaviruses
Causal effect questioned (Amstey) (Letter); (Carson) (Reply). 1990;162:868
Effect of the menstrual cycle on detection and typing of human papillomavirus in uterine cervical cells (McNicol et al). 1990;162:1037-41
Lichen sclerosus, invasive squamous cell carcinoma, and human papillomavirus (Neill et al). 1990;162:1633-4 (Letter)
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103
Remarks deemed overly critical of research by private practice physicians (Davison) (Letter); (Reid) (Reply). 1990;162:290-1
Temporal associations of human papillomavirus infection with cervical cytologic abnormalities (Lorincz et al). 1990;162:645-51
Underwear: contamination by human papillomaviruses (Bergeron et al). 1990;162:25-9
Paraplegia
Epidural analgesia and autonomic hyperreflexia: a case report (Katz et al). 1990;162:471-2
Parturition; *see* **Labor**
Pelvic inflammatory disease; *see* **Adnexitis**
Pelvic neoplasms
Pregnancy hemoperitoneum and placenta percreta in a patient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6
Pelvis
Is office use of vaginal ultrasonography feasible? (Timor-Tritsch). 1990;162:983-5 (Clin. opinion)
Pelviscopic adnexectomy (Perry and Upchurch). 1990;162:79-81
Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance (Lorenz et al). 1990;162:1603-10
Pelvis, surgery
Blood exposure in single versus double gloving during pelvic surgery (Cohn and Seifer). 1990;162:715-7
Modified cystoscopy to evaluate unilateral traumatic injury of the ureter during pelvic surgery (Lin and Iwata). 1990;162:1343-4 (Letter)
Single-dose antibiotic prophylaxis for patients undergoing extended pelvic surgery for gynecologic malignancy (Orr et al). 1990;162:718-21
Peptides
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8
Perinatal asphyxia; *see* **Asphyxia neonatorum**
Peritoneal cavity
CA 125 in peritoneal fluid (Williams) (Letter); (Dawood et al) (Reply). 1990;162:296
Peritoneoscopy
Cardiovascular collapse during laparoscopy (Lip and Delhaas) (Letter); (Brantley) (Reply). 1990;162:873

Peritoneoscopy—cont'd
Diagnosis and clinical presentation of endometriosis (Adamson). 1990;162:568-9 (Symposium)
Hysteroscopy and laparoscopy in women with menorrhagia (Fraser). 1990;162:1264-9
A modification of operative laparoscopic technique to permit removal of an ectopic pregnancy without morcellation (Eysler and Soper). 1990;162:1348 (Letter)
Pelviscopic adnexectomy (Perry and Upchurch). 1990;162:79-81
Reevaluation of the role of culdocentesis in the management of ectopic pregnancy (Vermesh et al). 1990;162:411-3
Short self-retaining trocar sleeves for laparoscopic surgery (Reich and McGlynn). 1990;162:453-4
Periventricular leukomalacia; *see* **Leukomalacia, periventricular**
Pessaries
The efficacy of oral mifepristone (RU-38,486) with a prostaglandin E_1 analog vaginal pessary for the termination of early pregnancy: complications and patient acceptability (Hill et al). 1990;162:414-7
pH; *see* **Hydrogen-ion concentration**
Phenytoin
Magnesium sulfate is the ideal anticonvulsant in preeclampsia-eclampsia (Sibai). 1990;162:1141-5 (Clin. opinion)
Phospholipids
Corticosteroid treatment of pregnant women with antiphospholipid antibodies and previous fetal loss (Lubbe and Pattison) (Letter); (Lockshin and Druzin) (Reply). 1990;162:1341-3
Need for a prospective treatment trial (Harris). 1990;162:1121 (Letter)
Pathophysiology of antiphospholipid antibodies: absence of prostaglandin-mediated effects on cultured endothelium (Dudley et al). 1990;162:953-9
The tap test: confirmation of a simple, rapid, inexpensive, and reliable indicator of fetal pulmonary maturity (Socol). 1990;162:218-22
Phosphorus isotopes
Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—preliminary data (Raman et al). 1990;162:1511-7
Physical examination
Incorporating endovaginal ultrasonography into the overall gynecologic examination (Goldstein). 1990;162:625-32 (Clin. opinion)
Prediction of preterm delivery: Is it substantially improved by routine vaginal examinations? (Blondel et al). 1990;162:1042-8
Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance (Lorenz et al). 1990;162:1603-10
Warning symptoms, uterine contractions, and cervical examination findings in women at risk of preterm delivery (Copper et al). 1990;162:748-54
Physician-patient relations
Clinical guides to preventing ethical conflicts between pregnant women and their physicians (Chervenak and McCullough). 1990;162:303-7 (Clin. opinion)
Physician's practice patterns
The Green Bay cesarean section study. I. The physician factor as a determinant of cesarean birth rates (DeMott and Sandmire). 1990;162:1593-602
Physician characteristics and cesarean delivery (Barton) (Letter); (Berkowitz) (Reply). 1990;162:1641-2
Sex bias inappropriate (Kay) (Letter); (Petrikovsky et al) (Reply). 1990;162:866
Physiological compensation; *see* **Adaptation, physiological**
Piperacillin
Antibiotic prophylaxis: Is there a difference? (Faro et al). 1990;162:900-9
Pituitary hormone releasing hormones, agonists
Comparison of the pharmacology of nafarelin and danazol (Barbieri). 1990;162:581-5 (Symposium)
Efficacy and safety of nafarelin in the treatment of endometriosis (Henzl and Kwei). 1990;162:570-4 (Symposium)
Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy (Barbieri). 1990;162:593-5 (Symposium)
Gonadotropin-releasing hormone analogs in the treatment of endometriomas (Schenken). 1990;162:579-81 (Symposium)
Nafarelin in the treatment of pelvic pain caused by endometriosis (Shaw). 1990;162:574-6 (Symposium)
Pituitary hormone releasing hormones, antagonists and inhibitors
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
Placenta
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Feasibility of placental biopsy in the second trimester for fetal diagnosis (Saura et al) (Letter); (Chieri) (Reply). 1990;162:1362-3
HBsAg in placentas (Lin) (Letter); (Lucifora) (Reply). 1990;162:1361
Immunocytochemical localization and messenger ribonucleic acid concentrations for human placental lactogen in amnion, chorion, decidua, and placenta (Sakbun et al). 1990;162:1310-7
The placenta in the litigation process (Benirschke). 1990;162:1445-50
Placental deposits of stainable iron (Knisely) (Letter); (Birkenfeld et al) (Reply). 1990;162:1638-9
Placental transfer of indomethacin in the human pregnancy (Moise et al). 1990;162:549-54
The relationship between the umbilical artery systolic/diastolic ratio and umbilical blood gas measurements in specimens obtained by cordocentesis (Weiner). 1990;162:1198-202
Volume and timing are key to use of intraumbilical oxytocin for management of retained placenta (Golan). 1990;162:1628-9 (Letter)
Placenta, animal
Relationship between placental location and uterine vascular resistance (Perales) (Letter); (Kofinas) (Reply). 1990;162:1362
Placenta diseases
Demonstration of Fabry's disease deposits in placenta (Popli et al). 1990;162:464-5
Immunohistologic evidence that villitis in human normal term placentas is an immunologic lesion (Labarrere et al). 1990;162:515-22
Placenta praevia
Pregnancy hemoperitoneum and placenta percreta in a pa-

tient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6

Placental biopsy; *see* **Chorionic villi sampling**

Placental function tests

Fetal hemodynamic and fetoplacental vascular response to exogenous arginine vasopressin (Irion et al). 1990;162:1115-20

Placental hormones

Placental production of estradiol and progesterone after oocyte donation in patients with primary ovarian failure (Devroey et al). 1990;162:66-70

Placental lactogen

Immunocytochemical localization and messenger ribonucleic acid concentrations for human placental lactogen in amnion, chorion, decidua, and placenta (Sakbun et al). 1990;162:1310-7

Plasma exchange

Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37

Pregnancy in a homozygous familial hypercholesterolemic patient treated with long-term plasma exchange (Beigel et al). 1990;162:77-8

Plasma volume

Need for plasma volume estimation (Goodlin). 1990;162:601 (Letter)

Platelet activating factor

Detection of platelet-activating factor in amniotic fluid of complicated pregnancies (Hoffman et al). 1990;162:525-8

Platelet count

The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)

Is sampling technique beneficial to fetus? (Lenke and Deveny) (Letter); (Scioscia et al) (Reply). 1990;162:597-8

Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3

Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37

Platelet count in normal, small, and anemic fetuses (Van den Hof and Nicolaides). 1990;162:735-9

Pneumatometra; *see* **Uterus, abnormalities**

Pneumonia, *Pneumocystis carinii*

Serious infections during pregnancy among women with advanced human immunodeficiency virus infection (Minkoff et al). 1990;162:30-4

Poloxamer 407

Reduction of postoperative adhesions in the rat uterine horn model with poloxamer 407 (Leach and Henry). 1990;162:1317-9

Polyhydramnios; *see* **Hydramnios**

Postcoital test; *see* **Cervix mucus**

Postmenopause; *see* **Menopause**

Postoperative care

Leiomyosarcoma in a series of hysterectomies performed for presumed uterine leiomyomas (Leibsohn et al). 1990;162:968-76

Postoperative complications

Bilateral compartment syndrome after a long gynecologic operation in the lithotomy position (Adler et al). 1990;162:1271-2

Modified cystoscopy to evaluate unilateral traumatic injury of the ureter during pelvic surgery (Lin and Iwata). 1990;162:1343-4 (Letter)

Reduction of postoperative adhesions in the rat uterine horn model with poloxamer 407 (Leach and Henry). 1990;162:1317-9

Sacrospinous ligament fixation at the time of transvaginal hysterectomy (Cruikshank and Cox). 1990;162:1611-9

Postpartum period; *see* **Puerperium**

Pre-eclampsia

Acute renal failure in hypertensive disorders of pregnancy (Sibai et al). 1990;162:777-83

Anti-vascular endothelial cell antibodies in severe preeclampsia (Rappaport et al). 1990;162:138-46

The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)

Increased plasma levels of $ED1^+$ cellular fibronectin precede the clinical signs of preeclampsia (Lockwood and Peters). 1990;162:358-62

Increasing quantity of maternal immunoglobulin G in trophoblastic tissue before the onset of normal labor (Akin et al). 1990;162:1154-7

Lack of association of cytotoxicity in serum and preeclampsia (Frohlich) (Letter); (Roberts and Taylor) (Reply). 1990;162:873-4

Magnesium plus nifedipine (Ales) (Letter); (Waisman) (Reply). 1990;162:288

Magnesium sulfate is the ideal anticonvulsant in preeclampsia-eclampsia (Sibai). 1990;162:1141-5 (Clin. opinion)

Mitochondrial myopathy and preeclampsia associated with pregnancy (Berkowitz et al). 1990;162:146-7

Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37

Pulmonary artery catheterization in severe preeclampsia (Goodlin) (Letter); (Clark and Cotton) (Reply). 1990;162:601-3

Reliance on central venous pressure with regard to fluid management in preeclampsia deemed dangerous (Clark). 1990;162:598 (Letter)

Significance of uric acid clearance in preeclampsia (Yoshimura et al). 1990;162:1639-40 (Letter)

The use of nifedipine during the postpartum period in patients with severe preeclampsia (Barton et al). 1990;162:788-92

The value of Doppler assessment of the uteroplacental circulation in predicting preeclampsia or intrauterine growth retardation (Jacobson et al). 1990;162:110-4

Predictive value of tests

The abnormal fetal biophysical profile score. V. Predictive accuracy according to score composition (Manning et al). 1990;162:918-27

The association of fetal and newborn metabolic acidosis with severe periventricular leukomalacia in the preterm newborn (Low et al). 1990;162:977-82

Fetal assessment based on fetal biophysical profile scoring. III. Positive predictive accuracy of the very abnormal test (biophysical profile score = 0) (Manning et al). 1990;162:398-402

Poor predictive value of symphysial-fundal height when misused in clinical practice (Belizan et al). 1990;162:1348-9 (Letter)

The tap test: confirmation of a simple, rapid, inexpensive,

Predictive value of tests—cont'd
and reliable indicator of fetal pulmonary maturity (Socol). 1990;162:218-22
Prednisone
Corticosteroid treatment of pregnant women with antiphospholipid antibodies and previous fetal loss (Lubbe and Pattison) (Letter); (Lockshin and Druzin) (Reply). 1990;162:1341-3
Efficacy of prednisone treatment to prevent recurrent fetal death (Cowchock and Balaban) (Letter); (Lockshin et al) (Reply). 1990;162:1128-9
Need for a prospective treatment trial (Harris). 1990;162:1121 (Letter)
Pregnancy
The amniotic fluid index in normal human pregnancy (Moore and Cayle). 1990;162:1168-73
Assessment of fetal response to exercise in pregnancy (Rafla) (Letter); (Morrow) (Reply). 1990;162:1129-30
Cardiovascular response to maximal cycle exercise during pregnancy and at two and seven months post partum (Sady et al). 1990;162:1181-5
Cervical length may change during ultrasonographic examination (Sonek et al). 1990;162:1355-7 (Letter)
Changes in uterine blood flow during human pregnancy (Thaler et al). 1990;162:121-5
Different characteristics of amniotic and cervical collagenous tissue during pregnancy and delivery: a morphologic study (Yoshida and Manabe). 1990;162:190-3
Increase in the plasma levels of the N-terminal and C-terminal portions of the prohormone of atrial natriuretic factor during normal pregnancy (Merkouris et al). 1990;162:859-64
Prepregnancy weight status, prenatal weight gain, and the outcome of term twin gestations (Brown and Schloesser). 1990;162:182-6
Some electrical properties of human pregnant myometrium (Inoue et al). 1990;162:1090-8
Theoretical and technical questions involved with hemodynamic responses (Clapp) (Letter); (Morrow) (Reply). 1990;162:867-8
Vaginal ultrasonographic assessment of cervical length changes during normal pregnancy (Kushnir et al). 1990;162:991-3
Pregnancy, animal
α_2-Adrenergic receptors in guinea pig myometrium in late pregnancy: evidence for a predominantly postjunctional location (Arkinstall et al). 1990;162:831-6
Characterization of norepinephrine sensitivity in the maternal splanchnic circulation during pregnancy (Crandall et al). 1990;162:1296-301
Direct determination of the ovine fetal umbilical artery blood flow waveform (Irion and Clark). 1990;162:541-9
Intrauterine asphyxia and the breakdown of physiologic circulatory compensation in fetal sheep (Block et al). 1990;162:1325-31
Pregnancy does not alter lidocaine toxicity (Morishima et al). 1990;162:1320-4
Pregnancy, drug effects
Pharmacokinetics of ritodrine administered intravenously: recommendations for changes in the current regimen (Caritis et al). 1990;162:429-37
Pregnancy, ectopic
Causes of the increase in ectopic pregnancy (Atrash and Franks) (Letter); (Mäkinen et al) (Reply). 1990;162:1130-2
Conservative management of cervical pregnancy with subsequent fertility (Bachus et al). 1990;162:450-1
Ectopic pregnancy concurrent with induced abortion: incidence and mortality (Atrash et al). 1990;162:726-30
A modification of operative laparoscopic technique to permit removal of an ectopic pregnancy without morcellation (Eysler and Soper). 1990;162:1348 (Letter)
Reevaluation of the role of culdocentesis in the management of ectopic pregnancy (Vermesh et al). 1990;162:411-3
Reproductive performance after methotrexate treatment of ectopic pregnancy (Stovall et al). 1990;162:1620-4
Vaginal ultrasonography in the diagnosis of ectopic pregnancy (Frishman and Luciano) (Letter); (Timor-Tritsch) (Reply). 1990;162:1640-1
Pregnancy, multiple
Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6
Hydramnios in twin pregnancy (Machin and Still). 1990;162:1625-6 (Letter)
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9
Selective termination: clinical experience and residual risks (Evans et al). 1990;162:1568-75
Seventy-one quadruplet pregnancies: management and outcome (Collins and Bleyl). 1990;162:1384-92
Treatment of twins with hydramnios (Thorp and Chescheir) (Letter); (Lange and Harman) (Reply). 1990;162:1625
Pregnancy, tubal
Cesarean salpingectomy rare but not first (Pelosi). 1990;162:605-6 (Letter)
Pregnancy complications
Amniotic fluid α_1-antitrypsin concentration in premature rupture of the membranes (O'Brien et al). 1990;162:756-9
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Conservative management of cervical pregnancy with subsequent fertility (Bachus et al). 1990;162:450-1
Contractions of the inner third of the myometrium (de Vries et al). 1990;162:679-82
Cushing's syndrome and pregnancy (Aron et al). 1990;162:244-52 (Curr. dev.)
Detection of platelet-activating factor in amniotic fluid of complicated pregnancies (Hoffman et al). 1990;162:525-8
Epidural analgesia and autonomic hyperreflexia: a case report (Katz et al). 1990;162:471-2
Heparin prophylaxis during pregnancy (Brill-Edwards et al) (Letter); (Bergqvist et al) (Reply). 1990;162:870-1
Increasing quantity of maternal immunoglobulin G in trophoblastic tissue before the onset of normal labor (Akin et al). 1990;162:1154-7
Intrapartum asphyxia in the preterm fetus <2000 gm (Low et al). 1990;162:378-82
Mitochondrial myopathy and preeclampsia associated with pregnancy (Berkowitz et al). 1990;162:146-7
Pharmacokinetics and pharmacodynamics of ritodrine after intramuscular administration to pregnant women (Caritis et al). 1990;162:1215-9

Prediction of fetoplacental blood volume in isoimmunized pregnancy (Leduc and Moise) (Letter); (MacGregor) (Reply). 1990;162:1124
Pregnancy hemoperitoneum and placenta percreta in a patient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6
Pregnancy outcome and fetomaternal hemorrhage after noncatastrophic trauma (Goodwin and Breen). 1990;162:665-71
A prospective controlled study of outcome after trauma during pregnancy (Pearlman et al). 1990;162:1502-10
A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9
Serum fructosamine and amniotic fluid insulin levels in patients with gestational diabetes and healthy control subjects (Hofmann et al). 1990;162:1174-7
Spontaneous resolution of Cushing's syndrome after pregnancy (Aron et al). 1990;162:472-4
Treatment in an obstetric intensive care unit (Mabie and Sibai). 1990;162:1-4 (Clin. opinion)
The use of nifedipine during the postpartum period in patients with severe preeclampsia (Barton et al). 1990;162:788-92
Vaginal bleeding and diethylstilbestrol exposure during pregnancy: relationship to genital tract clear cell adenocarcinoma and vaginal adenosis in daughters (Sharp and Cole). 1990;162:994-1001

Pregnancy complications, cardiovascular

A comparison of no medication versus methyldopa or labetalol in chronic hypertension during pregnancy (Sibai et al). 1990;162:960-7
Effects of hypoxemia with and without acidemia on the isometric contraction time and the electromechanical delay of the fetal myocardium: an experimental study on the ovine fetus (Fouron et al). 1990;162:262-6
Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7
Labetalol pharmacokinetics in pregnancy-induced hypertension (Rogers et al). 1990;162:362-6
A longitudinal study of maternal digoxin-like immunoreactive substances in normotensive pregnancy and pregnancy-induced hypertension (Kerkez et al). 1990;162:783-7
A longitudinal study of respiratory changes in normal human pregnancy with cross-sectional data on subjects with pregnancy-induced hypertension (Rees et al). 1990;162:826-30
Methodologic queries: clinical significance of mean arterial blood pressure in second trimester (Ales and Druzin) (Letter); (Sibai) (Reply). 1990;162:876-7
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162:1065-6
The relationship of maternal erythrocyte oxygen transport parameters to intrauterine growth retardation (Brown et al). 1990;162:223-9
Thromboprophylaxis during pregnancy (Hellgren et al). 1990;162:1338-9 (Letter)
Transient oligohydramnios in a severely hypovolemic gravid woman at 35 weeks' gestation, with fluid reaccumulating immediately after intravenous maternal hydration (Sherer et al). 1990;162:770-1
Use of digoxin in pregnancy (De Lia and Emery) (Letter); (Weiner) (Reply). 1990;162:606-8

Pregnancy complications, cardiovascular, animal

Pregnancy increases cardiovascular toxicity to cocaine (Woods and Plessinger). 1990;162:529-33
The relationship between experimentally determined litter size and maternal blood pressure in spontaneously hypertensive rats (Ahokas and Sibai). 1990;162:841-7

Pregnancy complications, hematologic

The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)
Management of isoimmunized pregnancy by use of intravascular techniques (Porto et al) (Letter); (Barss) (Reply). 1990;162:292-3
Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3
Need for plasma volume estimation (Goodlin). 1990;162:601 (Letter)
Placental deposits of stainable iron (Knisely) (Letter); (Birkenfeld et al) (Reply). 1990;162:1638-9
Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37
Resolution of severe thrombocytopenia in a pregnant patient with rhesus-negative blood with autoimmune thrombocytopenic purpura after intravenous rhesus immune globulin (Moise et al). 1990;162:1237-8
Thrombocytopenia at delivery: a prospective survey of 6715 deliveries (Burrows and Kelton). 1990;162:731-4
Vel isoimmunization in pregnancy (Stiller et al). 1990;162:1071-2

Pregnancy complications, infectious

Chlamydia trachomatis infection in pregnancy and effect of treatment on outcome (Ryan et al). 1990;162:34-9
Fetal cytomegalovirus infection: a case report (Meisel et al). 1990;162:663-4
Production of prostaglandin E_2 by human amnion in vitro in response to addition of media conditioned by microorganisms associated with chorioamnionitis and preterm labor (Lamont et al). 1990;162:819-25
Serious infections during pregnancy among women with advanced human immunodeficiency virus infection (Minkoff et al). 1990;162:30-4

Pregnancy complications, neoplastic

Gestational trophoblastic disease: What have we learned in the past decade? (Jones). 1990;162:1286-95
Vulvar leiomyosarcoma in pregnancy (Kuller et al). 1990;162:164-6

Pregnancy in diabetes

Accelerated starvation in late pregnancy: a comparison between obese women with and without gestational diabetes mellitus (Buchanan et al). 1990;162:1015-20
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Fructosamine assay as screening test for gestational diabetes (Kaufman) (Letter); (Comtois and Desjarlais) (Reply). 1990;162:1339-41
Fructosamine in gestational diabetes (Doery et al) (Letter); (Comtois and Desjarlais) (Reply). 1990;162:1635-6
Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14

Pregnancy in diabetes—cont'd
Serum fructosamine and amniotic fluid insulin levels in patients with gestational diabetes and healthy control subjects (Hofmann et al). 1990;162:1174-7
Pregnancy maintenance
Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance (Lorenz et al). 1990;162:1603-10
Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes (Novy et al). 1990;162:1412-20
Pregnancy outcome
Active management of labor (Lynch) (Letter); (Leveno et al) (Reply). 1990;162:1637-8
Acute renal failure in hypertensive disorders of pregnancy (Sibai et al). 1990;162:777-83
Chlamydia trachomatis infection in pregnancy and effect of treatment on outcome (Ryan et al). 1990;162:34-9
Comparative evaluation of uterine response to exercise on five aerobic machines (Durak et al). 1990;162:754-6
Conclusions lack support (Goodlin) (Letter); (Mueller-Heubach) (Reply). 1990;162:1627-8
The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: a prospective blinded study (Maulik et al). 1990;162:1518-25
Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality (Manning et al). 1990;162:703-9
Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention (Crombleholme et al). 1990;162:1239-44
Maternal serum α-fetoprotein in twin pregnancy (Johnson et al). 1990;162:1020-5
Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries (Robertson et al). 1990;162:1436-44
Neonatal outcome after prolonged preterm rupture of the membranes (Rotschild et al). 1990;162:46-52
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9
Ovulation and successful pregnancy in a woman with ovarian failure after hypophysectomy and gonadotropin therapy (Check). 1990;162:775-6
Placental production of estradiol and progesterone after oocyte donation in patients with primary ovarian failure (Devroey et al). 1990;162:66-70
Pregnancy outcome and fetomaternal hemorrhage after noncatastrophic trauma (Goodwin and Breen). 1990;162:665-71
Prepregnancy weight status, prenatal weight gain, and the outcome of term twin gestations (Brown and Schloesser). 1990;162:182-6
A prospective controlled study of outcome after trauma during pregnancy (Pearlman et al). 1990;162:1502-10
Proteinuria and outcome of 444 pregnancies complicated by hypertension (Ferrazzani et al). 1990;162:366-71
Seventy-one quadruplet pregnancies: management and outcome (Collins and Bleyl). 1990;162:1384-92
Successful pregnancy and normal delivery with Marlex mesh replacement of the abdominal wall (Ezra et al). 1990;162:97-8
Surrogate pregnancy: clinical features of forty-four cases (Reame and Parker). 1990;162:1220-5
Pregnancy trimester, first
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
Embryoscopy: description and utility of a new technique (Cullen et al). 1990;162:82-6
First-trimester diagnosis of exencephaly (Kennedy et al). 1990;162:461-3
Prediction of residual trophoblastic tissue in first-trimester abortions and low levels of human chorionic gonadotropin β-subunit (Schiff et al). 1990;162:797-801
Very high CA 125 levels during early first trimester in three cases of spontaneous abortion with chromosomal abnormalities (Check et al). 1990;162:674-5
Pregnancy trimester, second
Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Feasibility of placental biopsy in the second trimester for fetal diagnosis (Saura et al) (Letter); (Chieri) (Reply). 1990;162:1362-3
Intrafetal prostaglandin $F_{2\alpha}$ administration for midtrimester pregnancy termination: a case report (Christodoulou et al). 1990;162:1245-6
Pregnancy trimester, third
Accelerated starvation in late pregnancy: a comparison between obese women with and without gestational diabetes mellitus (Buchanan et al). 1990;162:1015-20
Antepartum heart rate patterns in small-for-gestational-age third-trimester fetuses: correlations with blood gas values obtained at cordocentesis (Visser et al). 1990;162:698-703
Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92
Comparative evaluation of uterine response to exercise on five aerobic machines (Durak et al). 1990;162:754-6
Hydramnios in the third trimester of pregnancy: a change in the distribution of accompanying fetal anomalies as a result of early ultrasonographic prenatal diagnosis (Ben-Chitrit et al). 1990;162:1344-5 (Letter)
Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes (Buchanan et al). 1990;162:1008-14
Premature infant; *see* Infant, premature
Premature labor; *see* Labor, premature
Premature ovarian failure; *see* Ovarian diseases
Premature rupture of membranes; *see* Fetal membranes, premature rupture
Premenstrual syndrome
The effect of hysterectomy and bilateral oophorectomy in women with severe premenstrual syndrome (Casper and Hearn). 1990;162:105-9
Lasting response to ovariectomy in severe intractable premenstrual syndrome (Casson et al). 1990;162:99-105
Prenatal care
Prepregnancy weight status, prenatal weight gain, and the outcome of term twin gestations (Brown and Schloesser). 1990;162:182-6
Prenatal diagnosis
An analysis of antenatal tests to detect infection in preterm

premature rupture of the membranes (Ohlsson and Wang). 1990;162:809-18 (Curr. dev.)
Analysis of indications for referral to a multidisciplinary medical genetics clinic: implications for training programs in obstetrics and gynecology (Bombard et al). 1990;162:10-4
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Biparietal diameter/femur length ratio as predictor of trisomy 21 (Kopelman and Miyazawa). 1990;162:1346 (Letter)
Cytogenetic results of chorionic villus sampling: high success rate and diagnostic accuracy in the United States collaborative study (Ledbetter et al). 1990;162:495-501 (Curr. invest.)
The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: a prospective blinded study (Maulik et al). 1990;162:1518-25
Early prenatal diagnosis of gastroschisis with transvaginal ultrasonography (Guzman). 1990;162:1253-4
Embryoscopy: description and utility of a new technique (Cullen et al). 1990;162:82-6
An evaluation of the efficacy of Doppler flow velocity waveform analysis as a screening test in pregnancy (Newnham et al). 1990;162:403-10
Evaluation of the lemon and banana signs in one hundred thirty fetuses with open spina bifida (Van den Hof et al). 1990;162:322-7
Feasibility of placental biopsy in the second trimester for fetal diagnosis (Saura et al) (Letter); (Chieri) (Reply). 1990;162:1362-3
Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52
Fetal cytomegalovirus infection: a case report (Meisel et al). 1990;162:663-4
First-trimester diagnosis of exencephaly (Kennedy et al). 1990;162:461-3
Hydramnios in the third trimester of pregnancy: a change in the distribution of accompanying fetal anomalies as a result of early ultrasonographic prenatal diagnosis (Ben-Chitrit et al). 1990;162:1344-5 (Letter)
Intracranial teratoma: prolonged neonatal survival after prenatal diagnosis (Dolkart et al). 1990;162:768-9
Prediction of preterm delivery: Is it substantially improved by routine vaginal examinations? (Blondel et al). 1990;162:1042-8
Prenatal diagnosis of intracerebellar hemorrhage: case report (Jennett et al). 1990;162:1472-5
Prenatal diagnosis of valvar aortic stenosis by Doppler echocardiography and magnetic resonance imaging (Hata et al). 1990;162:1068-70
Sonographic findings in the prenatal diagnosis of bladder exstrophy (Jaffe et al). 1990;162:675-8
Ultrasonography-guided early amniocentesis in singleton pregnancies (Hanson et al). 1990;162:1376-83

Preterm delivery; *see* **Infant, premature**

Preterm fetus; *see* **Fetal development**

Preterm infant; *see* **Infant, premature**

Preterm labor; *see* **Labor, premature**

Professional practice
Men without chests (Maxwell). 1990;162:1499-501 (Pres. address)
Scientific advances, societal trends, and the education and practice of obstetrician-gynecologists (Willson). 1990;162:1135-40 (Clin. opinion)

Progesterone
Cytokine-mediated regulation of ovarian function: tumor necrosis factor α inhibits gonadotropin-supported progesterone accumulation by differentiating and luteinized murine granulosa cells (Adashi et al). 1990;162:889-99
Designing a schedule of progestin administration in the control of endometrial carcinoma growth in the nude mouse model (Mortel et al). 1990;162:928-36
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103
Placental production of estradiol and progesterone after oocyte donation in patients with primary ovarian failure (Devroey et al). 1990;162:66-70
In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14

Progesterone, antagonists and inhibitors
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
The effects of RU-38486 on cervical ripening (Lefebvre et al). 1990;162:61-5
The efficacy of oral mifepristone (RU-38,486) with a prostaglandin E_1 analog vaginal pessary for the termination of early pregnancy: complications and patient acceptability (Hill et al). 1990;162:414-7
Orosomucoid in human pregnancy serum diminishes bioavailability of the progesterone antagonist RU 486 in rats (Steingold et al). 1990;162:523-4
Predictors of failed attempted abortion with the antiprogestin mifepristone (RU 486) (Grimes et al). 1990;162:910-7

Progesterone hormones, synthetic
Evaluation of a continuous combined low-dose regimen of estrogen-progestin for treatment of the menopausal patient (Weinstein et al). 1990;162:1534-42

Progesterone receptors; *see* **Receptors, progesterone**

Progestin; *see* **Progesterone hormones, synthetic**

Prolactin
The neuropeptide histidyl proline diketopiperazine throughout human pregnancy: an inverse correlation with amniotic fluid prolactin (Wolf et al). 1990;162:740-5
Suppressive actions of a gonadotropin-releasing hormone antagonist on luteinizing hormone, follicle-stimulating hormone, and prolactin release in estrogen-deficient postmenopausal women (Urban et al). 1990;162:1255-60
In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14

Prolactin, animal
The effect of prolactin on murine in vitro fertilization and embryo development (Dodds et al). 1990;162:1553-61

Prolactinoma
Ovulation and successful pregnancy in a woman with ovarian failure after hypophysectomy and gonadotropin therapy (Check). 1990;162:775-6

Proline
The neuropeptide histidyl proline diketopiperazine throughout human pregnancy: an inverse correlation

Proline—cont'd
with amniotic fluid prolactin (Wolf et al). 1990;162: 740-5
Prospective studies
The conservative management of patients with symptoms of stress incontinence: a randomized, prospective study comparing weighted vaginal cones and interferential therapy (Oláh et al). 1990;162:87-92
A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9
Thrombocytopenia at delivery: a prospective survey of 6715 deliveries (Burrows and Kelton). 1990;162:731-4
Prostaglandin synthase, antagonists and inhibitors
Oligohydramnios in each sac of a triplet gestation caused by Motrin—fulfilling Kock's postulates (Wiggins and Elliott). 1990;162:460-1
Prostaglandins E
The efficacy of oral mifepristone (RU-38,486) with a prostaglandin E_1 analog vaginal pessary for the termination of early pregnancy: complications and patient acceptability (Hill et al). 1990;162:414-7
Management of severe postpartum hemorrhage by intrauterine irrigation with prostaglandin E_2 (Peyser and Kupferminc). 1990;162:694-6
Mechanisms of parturition: the transfer of prostaglandin E_2 and 5-hydroxyeicosatetraenoic acid across fetal membranes (Bennett et al). 1990;162:683-7
Myometrial activity after local application of prostaglandin E_2 for cervical ripening and term labor induction (Granström et al). 1990;162:691-4
Production of prostaglandin E_2 by human amnion in vitro in response to addition of media conditioned by microorganisms associated with chorioamnionitis and preterm labor (Lamont et al). 1990;162:819-25
Prostaglandins F
Pathophysiology of antiphospholipid antibodies: absence of prostaglandin-mediated effects on cultured endothelium (Dudley et al). 1990;162:953-9
Prostaglandins F, synthetic
Controlling refractory atonic postpartum hemorrhage with Hemabate sterile solution (Oleen and Mariano). 1990;162:205-8
Intrafetal prostaglandin $F_{2\alpha}$ administration for midtrimester pregnancy termination: a case report (Christodoulou et al). 1990;162:1245-6
Prostaglandins X
The influence of drugs with β-adrenergic actions on prostacyclin production of human umbilical cord vessels (Lippert et al). 1990;162:288-90 (Letter)
Pathophysiology of antiphospholipid antibodies: absence of prostaglandin-mediated effects on cultured endothelium (Dudley et al). 1990;162:953-9
Proteinuria
Proteinuria and outcome of 444 pregnancies complicated by hypertension (Ferrazzani et al). 1990;162:366-71
Pseudogenes
Pseudogene/functional gene ratio in late-onset 21-hydroxylase-deficient adrenal hyperplasia (Azziz et al). 1990;162:633-8
Pubic symphysis
The mons pubis: an excellent graft donor site in gynecologic surgery (Dudzinski and Rader). 1990;162:722-5
Poor predictive value of symphysial-fundal height when misused in clinical practice (Belizan et al). 1990;162:1348-9 (Letter)
Puerperal infection
A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9
Puerperium
Absence of perineal pain does not rule out puerperal hematoma (Harris) (Letter); (Chin) (Reply). 1990;162: 1357-8
Bacteriuria in the puerperium (Stray-Pedersen et al). 1990;162:792-7
Cardiovascular response to maximal cycle exercise during pregnancy and at two and seven months post partum (Sady et al). 1990;162:1181-5
Changes in hemostasis activity during delivery and the immediate postpartum period (Gerbasi et al). 1990;162:1158-63
Need for plasma volume estimation (Goodlin). 1990;162:601 (Letter)
Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37
Postpartum Budd-Chiari syndrome with prolonged hypercoagulability state (Ilan et al). 1990;162:1164-5
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162: 1065-6
Postpartum gentamicin dosing and endometritis (Stoukides and Souney) (Letter); (Briggs et al) (Reply). 1990;162:1132-3
Postpartum pulmonary embolus as an unusual cause of cortical blindness (Stiller et al). 1990;162:696-7
The use of nifedipine during the postpartum period in patients with severe preeclampsia (Barton et al). 1990;162:788-92
Pulmonary artery catheterization; *see* **Catheterization, Swan-Ganz**
Pulmonary edema
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162:1065-6
Pulmonary embolism
Fatal pulmonary embolism during legal induced abortion in the United States from 1972 to 1985 (Lawson et al). 1990;162:986-90
Postpartum pulmonary embolus as an unusual cause of cortical blindness (Stiller et al). 1990;162:696-7
Pulmonary hypoplasia, fetal; *see* **Fetal organ maturity**
Pulsatile flow
The effect of indomethacin on the pulsatility index of the umbilical artery in human fetuses (Moise et al). 1990;162:199-202
Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4
Purpura, thrombocytopenic
Resolution of severe thrombocytopenia in a pregnant patient with rhesus-negative blood with autoimmune thrombocytopenic purpura after intravenous rhesus immune globulin (Moise et al). 1990;162:1237-8

Q

Quadruplets
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9

Seventy-one quadruplet pregnancies: management and outcome (Collins and Bleyl). 1990;162:1384-92

Questionnaires
Sex bias inappropriate (Kay) (Letter); (Petrikovsky et al) (Reply). 1990;162:866

Quintuplets
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9

R

Radiation injuries
Pregnancy hemoperitoneum and placenta percreta in a patient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6

Radiotherapy, interstitial; *see* **Brachytherapy**

Rapid eye movement sleep; *see* **Sleep, REM**

***RAS* genes**
Oncogenic transformation by human papillomavirus type 16 deoxyribonucleic acid in the presence of progesterone or progestins from oral contraceptives (Pater et al). 1990;162:1099-103

Receptors, adrenergic
Characterization of norepinephrine sensitivity in the maternal splanchnic circulation during pregnancy (Crandall et al). 1990;162:1296-301

Receptors, adrenergic, alpha
α_2-Adrenergic receptors in guinea pig myometrium in late pregnancy: evidence for a predominantly postjunctional location (Arkinstall et al). 1990;162:831-6

Receptors, adrenergic, beta, animal
Rabbit alveolar β-adrenergic receptors increase with gestational age (Lewis et al). 1990;162:269-72

Receptors, progesterone
Designing a schedule of progestin administration in the control of endometrial carcinoma growth in the nude mouse model (Mortel et al). 1990;162:928-36

Recovery room
Use of the labor-delivery-recovery room in an urban tertiary care hospital (Williams and Mervis). 1990;162:23-4

Red blood cell alloimmunization; *see* **Erythroblastosis, fetal**

Relaxin
Effects of relaxin on calcium concentrations (Young) (Letter); (Goldsmith) (Reply). 1990;162:605

Renal failure, acute; *see* **Kidney failure, acute**

Renin-angiotensin system
Activation of the renin-angiotensin system during ritodrine treatment in preterm labor (Hanssens et al). 1990;162:1048-53

Reproduction techniques
Ethics and reproduction (Macnaughton). 1990;162:879-82

Reproductive potential; *see* **Fertilization**

Research
Remarks deemed overly critical of research by private practice physicians (Davison) (Letter); (Reid) (Reply). 1990;162:290-1

Research design
Effects of selection bias on outcomes at referral centers (Sepkowitz) (Letter); (Lubchenco) (Reply). 1990;162:1629-31

Residency, medical; *see* **Internship and residency**

Respiration
A longitudinal study of respiratory changes in normal human pregnancy with cross-sectional data on subjects with pregnancy-induced hypertension (Rees et al). 1990;162:826-30

Respiratory distress syndrome
Perinatal factors associated with the respiratory distress syndrome (Bryan et al). 1990;162:476-81

Respiratory distress syndrome, adult
Disseminated intravascular coagulopathy and adult respiratory distress syndrome: life-threatening complications of hysteroscopy (Jedeikin et al). 1990;162:44-5

Retained placenta; *see* **Placenta**

Retroperitoneal neoplasms
Case of retroperitoneal mucinous cystadenoma omitted (Cruikshank) (Letter); (Pennell) (Reply). 1990;162:1351-3

Rh isoimmunization; *see also* **Erythroblastosis, fetal**
Efficacy of management of isoimmunization with fetal umbilical blood sampling remains unproved (Deveny and Lenke). 1990;162:297-8 (Letter)
Management of isoimmunized pregnancy by use of intravascular techniques (Porto et al) (Letter); (Barss) (Reply). 1990;162:292-3
Prediction of fetoplacental blood volume in isoimmunized pregnancy (Leduc and Moise) (Letter); (MacGregor) (Reply). 1990;162:1124
Resolution of severe thrombocytopenia in a pregnant patient with rhesus-negative blood with autoimmune thrombocytopenic purpura after intravenous rhesus immune globulin (Moise et al). 1990;162:1237-8

Rhesus immune globulin; *see* **Immunization, passive**

Risk factors
Bacteriuria in the puerperium (Stray-Pedersen et al). 1990;162:792-7
Bilateral ovarian neoplasms and the risk of malignancy (Koonings et al). 1990;162:167-9
Cigarette smoking as a risk factor for pelvic inflammatory disease (Marchbanks et al). 1990;162:639-44
A comparison between umbilical artery velocimetry and standard antepartum surveillance in hospitalized high-risk patients (Lowery et al). 1990;162:710-4
Controlling refractory atonic postpartum hemorrhage with Hemabate sterile solution (Oleen and Mariano). 1990;162:205-8
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43
Intrauterine growth retardation and preterm delivery: prenatal risk factors in an indigent population (Wen et al). 1990;162:213-8
Prediction of preterm delivery: Is it substantially improved by routine vaginal examinations? (Blondel et al). 1990;162:1042-8
Selective termination: clinical experience and residual risks (Evans et al). 1990;162:1568-75
Warning symptoms, uterine contractions, and cervical examination findings in women at risk of preterm delivery (Copper et al). 1990;162:748-54

Risk management
Hysterectomy: a medical-legal perspective, 1975 to 1985 (Whitelaw). 1990;162:1451-8
The placenta in the litigation process (Benirschke). 1990;162:1445-50

Ritodrine
Activation of the renin-angiotensin system during ritodrine treatment in preterm labor (Hanssens et al). 1990;162:1048-53
Calculation of ritodrine half-life (Ross) (Letter); (Caritis and Venkataramanan) (Reply). 1990;162:1643-4

Ritodrine—cont'd
Pharmacokinetics and pharmacodynamics of ritodrine after intramuscular administration to pregnant women (Caritis et al). 1990;162:1215-9
Pharmacokinetics of ritodrine administered intravenously: recommendations for changes in the current regimen (Caritis et al). 1990;162:429-37
Roster
Roster of American obstetric and gynecologic societies. 1990;162:299-300
RU-486
Could antiprogesterones be used as alternative cervical ripening agents? (Johnson and Bryce). 1990;162:688-90
The effects of RU-38486 on cervical ripening (Lefebvre et al). 1990;162:61-5
The efficacy of oral mifepristone (RU-38,486) with a prostaglandin E_1 analog vaginal pessary for the termination of early pregnancy: complications and patient acceptability (Hill et al). 1990;162:414-7
Orosomucoid in human pregnancy serum diminishes bioavailability of the progesterone antagonist RU 486 in rats (Steingold et al). 1990;162:523-4
Predictors of failed attempted abortion with the antiprogestin mifepristone (RU 486) (Grimes et al). 1990;162:910-7

S

S phase; *see* **Interphase**
Sacrospinous ligament fixation; *see* **Ligaments, surgery**
Sacrum
Antenatal diagnosis of sacral agenesis syndrome in a pregnancy complicated by diabetes mellitus (Sonek et al). 1990;162:806-8
Intractable venous sacral hemorrhage: use of stainless steel thumbtacks to obtain hemostasis (Patsner and Orr). 1990;162:452
Sacrospinous ligament fixation at the time of transvaginal hysterectomy (Cruikshank and Cox). 1990;162:1611-9
Saline solution amnioinfusions; *see* **Sodium chloride**
Salpingitis
Treatment-dependent and treatment-independent pregnancy among women with periadnexal adhesions (Tulandi et al). 1990;162:354-7
Salpingostomy
Cesarean salpingectomy rare but not first (Pelosi). 1990;162:605-6 (Letter)
Pelviscopic adnexectomy (Perry and Upchurch). 1990;162:79-81
Sampling studies
Is sampling technique beneficial to fetus? (Lenke and Deveny) (Letter); (Scioscia et al) (Reply). 1990;162:597-8
Sarcoidosis
Coexistence of mucinous cystadenoma of the ovary and ovarian sarcoidosis (White et al). 1990;162:1284-5
Second trimester pregnancy; *see* **Pregnancy trimester, second**
Selection bias
Effects of selection bias on outcomes at referral centers (Sepkowitz) (Letter); (Lubchenco) (Reply). 1990;162:1629-31
Selective termination; *see* **Abortion, therapeutic**
Semen
The validity of the postcoital test (Griffith and Grimes). 1990;162:615-20 (Clin. opinion)
Severity of illness index
Predicting neonatal morbidity after perinatal asphyxia: a scoring system (Portman et al). 1990;162:174-82
Sex, infant
Birth weight discordancy in male-first and female-first pairs of unlike-sexed twins (Blickstein and Weissman). 1990;162:661-3
Does maternal genital herpes infection influence fetal gender? (McGregor and Leff). 1990;162:1346-7 (Letter)
Sex steroids; *see* **Steroids**
Shirodkar cerclage; *see* **Cervix incompetence**
Shock
Transient oligohydramnios in a severely hypovolemic gravid woman at 35 weeks' gestation, with fluid reaccumulating immediately after intravenous maternal hydration (Sherer et al). 1990;162:770-1
Shock, cardiogenic
Postpartum pulmonary embolus as an unusual cause of cortical blindness (Stiller et al). 1990;162:696-7
Shoulder
Shoulder dystocia: prevention and treatment (O'Leary and Leonetti). 1990;162:5-9 (Clin. opinion)
Shoulder dystocia; *see* **Dystocia**
SID; *see* **Sudden infant death**
Sigmoid neoplasms
Clear cell carcinoma of the sigmoid mesocolon: a tumor of the secondary müllerian system (Evans et al). 1990;162:161-3
Sims-Huhner test; *see* **Cervix mucus**
Skin transplantation
The mons pubis: an excellent graft donor site in gynecologic surgery (Dudzinski and Rader). 1990;162:722-5
Sleep, REM
Local cerebral blood flow is increased in rapid-eye-movement sleep in fetal sheep (Abrams et al). 1990;162:278-81
Small for gestational age infant; *see* **Infant, small for gestational age**
Smoking
The antiestrogenic effect of cigarette smoking in women (Baron et al). 1990;162:502-14 (Curr. dev.)
Cigarette smoking as a risk factor for pelvic inflammatory disease (Marchbanks et al). 1990;162:639-44
Smoking, maternal age, fetal growth, and gestational age at delivery (Wen et al). 1990;162:53-8
Smooth muscle; *see* **Muscle, smooth**
Social environment
Effects of birth weight and sociodemographic variables on mental development of neonatal intensive care unit survivors (Resnick et al). 1990;162:374-8
Socioeconomic factors
Black premature births, maternal hematocrits, and gestational age data (Sepkowitz) (Letter); (Leberman et al) (Reply). 1990;162:293-5
Strategies for the prevention of low birth weight (Kliegman et al). 1990;162:1073-83 (Curr. dev.)
Sodium chloride
A prospective randomized study of saline solution amnioinfusion (Owen et al). 1990;162:1146-9
Sound
Sound environment of the fetal sheep (Gerhardt et al). 1990;162:282-7
Specialties, medical
Scientific advances, societal trends, and the education and

practice of obstetrician-gynecologists (Willson). 1990;162:1135-40 (Clin. opinion)
Subspecialty of gynecologic oncology proposed to manage breast disease (Kelley). 1990;162:1638 (Letter)
Spectroscopy; *see* **Spectrum analysis**
Spectrum analysis
Studies on cervical intraepithelial neoplasia: the level of octadeca-9,11-dienoic acid and measurement of free radical content by electron spin resonance spectroscopy (Wickens et al). 1990;162:854-8
Sperm banks
Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting (DiMarzo et al). 1990;162:1483-90
Sperm-ovum interaction
Value of hamster egg penetration assay (Corson) (Letter); (Mao and Grimes) (Reply). 1990;162:865
Sperm penetration assay; *see* **Sperm-ovum interaction**
Spermatozoa
Pregnancy rates with fresh versus computer-controlled cryopreserved semen for artificial insemination by donor in a private practice setting (DiMarzo et al). 1990;162:1483-90
Studies of hexokinase activity in human and mouse oocyte (Tsutsumi et al). 1990;162:1301-4
Spermicide; *see* **Vaginal creams, foams and jellies**
Spina bifida
Evaluation of the lemon and banana signs in one hundred thirty fetuses with open spina bifida (Van den Hof et al). 1990;162:322-7
Maternal serum α-fetoprotein levels in pregnancies among black and white women with fetal open spina bifida: a United States Collaborative Study (Johnson et al). 1990;162:328-31
Splanchnic circulation
Characterization of norepinephrine sensitivity in the maternal splanchnic circulation during pregnancy (Crandall et al). 1990;162:1296-301
Standard of care; *see* **Risk management**
Starvation
Accelerated starvation in late pregnancy: a comparison between obese women with and without gestational diabetes mellitus (Buchanan et al). 1990;162:1015-20
Sterilization
Blood exposure in single versus double gloving during pelvic surgery (Cohn and Seifer). 1990;162:715-7
Sterilization, tubal
Bilateral compartment syndrome after a long gynecologic operation in the lithotomy position (Adler et al). 1990;162:1271-2
Steroid-21-hydroxylase
Pseudogene/functional gene ratio in late-onset 21-hydroxylase-deficient adrenal hyperplasia (Azziz et al). 1990;162:633-8
Steroids
Consensus Development Meeting: metabolic aspects of oral contraceptives of relevance for cardiovascular diseases (Skouby). 1990;162:1335-7 (Announ.)
In vitro induction of prolactin production and aromatase activity by gonadal steroids exclusively in the stroma of separated proliferative human endometrium (Randolph et al). 1990;162:1109-14
Streptococcus*, group B;** *see* ***Streptococcus agalactiae
Streptococcus agalactiae
GBS-test sensitivity questioned (Lester et al) (Letter); (Christensen and Christensen) (Reply). 1990;162:291
Substance abuse
Postpartum cardiovascular complications after bromocriptine and cocaine use (Bakht et al). 1990;162:1065-6
The prevalence of substance abuse in patients with suspected preterm labor (Ney et al). 1990;162:1562-7
Sudden infant death
A nested case-control study of oxytocin and sudden infant death syndrome (Kraus and Bulterys). 1990;162:604-5 (Letter)
Surgical gloves; *see* **Gloves, surgical**
Surgical instruments
Short self-retaining trocar sleeves for laparoscopic surgery (Reich and McGlynn). 1990;162:453-4
Surgical mesh
Successful pregnancy and normal delivery with Marlex mesh replacement of the abdominal wall (Ezra et al). 1990;162:97-8
Surgical wound infection
Infections complicating low-risk cesarean sections in community hospitals: efficacy of antimicrobial prophylaxis (Ehrenkranz et al). 1990;162:337-43
Surrogate mothers
Surrogate pregnancy: clinical features of forty-four cases (Reame and Parker). 1990;162:1220-5
Suture techniques
Mechanical performance of square knots and sliding knots in surgery: a comparative study (van Rijssel et al). 1990;162:93-7
Sympathetic nervous system, animal
α_2-Adrenergic receptors in guinea pig myometrium in late pregnancy: evidence for a predominantly postjunctional location (Arkinstall et al). 1990;162:831-6
Sympathomimetics
Activation of the renin-angiotensin system during ritodrine treatment in preterm labor (Hanssens et al). 1990;162:1048-53
Symphysial-fundal height; *see* **Pubic symphysis**
Syncytiotrophoblast; *see* **Trophoblast**
Systolic/diastolic ratio in umbilical artery; *see* **Flowmeters**

T

T lymphocytes, helper; *see* **Helper cells**
Tap test; *see* **Amniotic fluid**
Technology, medical
The tyranny of technology (Figge). 1990;162:1365-9 (Pres. address)
Telemetry
Patient-recorded domiciliary fetal monitoring (Lindsay et al). 1990;162:466-70
Teratogens
Maternal spermicide use and adverse reproductive outcome: a meta-analysis (Einarson et al). 1990;162:655-60
Teratoma
Intracranial teratoma: prolonged neonatal survival after prenatal diagnosis (Dolkart et al). 1990;162:768-9
Thalassemia
Placental deposits of stainable iron (Knisely) (Letter); (Birkenfeld et al) (Reply). 1990;162:1638-9
Theca cells
Expression of the human inhibin α-subunit gene in preovulatory granulosa-theca cells (Burns et al). 1990;162:273-7

Third trimester pregnancy; *see* Pregnancy trimester, third
Thrombocytopenia
The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): Much ado about nothing? (Sibai). 1990;162:311-6 (Clin. opinion)
Is sampling technique beneficial to fetus? (Lenke and Deveny) (Letter); (Scioscia et al) (Reply). 1990;162:597-8
Plasma exchange for preeclampsia. I. Postpartum use for persistently severe preeclampsia-eclampsia with HELLP syndrome (Martin et al). 1990;162:126-37
Platelet count in normal, small, and anemic fetuses (Van den Hof and Nicolaides). 1990;162:735-9
Reply to Weiner (1989;161:1091-2) (Daffos). 1990;162:298 (Letter)
Resolution of severe thrombocytopenia in a pregnant patient with rhesus-negative blood with autoimmune thrombocytopenic purpura after intravenous rhesus immune globulin (Moise et al). 1990;162:1237-8
Thrombocytopenia at delivery: a prospective survey of 6715 deliveries (Burrows and Kelton). 1990;162:731-4
Use of cordocentesis in fetal hemolytic disease and autoimmune thrombocytopenia (Weiner) (Letter); (Reece et al) (Reply). 1990;162:1126-8
Thromboembolism
Thromboprophylaxis during pregnancy (Hellgren et al). 1990;162:1338-9 (Letter)
Thrombophlebitis
Heparin prophylaxis during pregnancy (Brill-Edwards et al) (Letter); (Bergqvist et al) (Reply). 1990;162:870-1
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Thrombosis
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Tocolysis
Magnesium tocolysis: serum levels versus success (Madden et al). 1990;162:1177-80
Shirodkar cerclage in a multifactorial approach to the patient with advanced cervical changes (Novy et al). 1990;162:1412-20
Ultrasonography and external cephalic version at term (Donald and Barton). 1990;162:1542-7
Tocolytic agents; *see also* Indomethacin
Calculation of ritodrine half-life (Ross) (Letter); (Caritis and Venkataramanan) (Reply). 1990;162:1643-4
The influence of drugs with β-adrenergic actions on prostacyclin production of human umbilical cord vessels (Lippert et al). 1990;162:288-90 (Letter)
Magnesium tocolysis: serum levels versus success (Madden et al). 1990;162:1177-80
Perinatal factors associated with the respiratory distress syndrome (Bryan et al). 1990;162:476-81
Pharmacokinetics and pharmacodynamics of ritodrine after intramuscular administration to pregnant women (Caritis et al). 1990;162:1215-9
Total abdominal hysterectomy; *see* Hysterectomy
Toxoplasma
Natural immunoglobulin M antibodies against *Toxoplasma gondii* during pregnancy (Gussetti et al) (Letter); (Konishi) (Reply). 1990;162:1359-60
Toxoplasmosis
Natural immunoglobulin M antibodies against *Toxoplasma gondii* during pregnancy (Gussetti et al) (Letter); (Konishi) (Reply). 1990;162:1359-60
Transactions
Transactions of the eighth annual meeting of the American Gynecological and Obstetrical Society. 1990;162:879-982
Transactions of the fifty-seventh annual meeting of the Central Association of Obstetricians and Gynecologists. 1990;162:1499-624
Transactions of the fifty-sixth annual meeting of the Pacific Coast Obstetrical and Gynecological Society. 1990;162:1365-498
Transcapillary fluid dynamics; *see* Water-electrolyte balance
Trauma; *see* Wounds and injuries
Triamcinolone
Severe symmetric intrauterine growth retardation associated with the topical use of triamcinolone (Katz et al). 1990;162:396-7
Triglycerides
Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses (Economides et al). 1990;162:382-6
Triplets
Oligohydramnios in each sac of a triplet gestation caused by Motrin—fulfilling Kock's postulates (Wiggins and Elliott). 1990;162:460-1
The outcome of triplet, quadruplet, and quintuplet pregnancies managed in a perinatal unit: obstetric, neonatal, and follow-up data (Gonen et al). 1990;162:454-9
Trisomy
Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6
Biparietal diameter/femur length ratio as predictor of trisomy 21 (Kopelman and Miyazawa). 1990;162:1346 (Letter)
Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52
Trocar sleeves; *see* Surgical instruments
Trophoblast
Diagnostic and therapeutic curettage in gestational trophoblastic disease (Schlaerth et al). 1990;162:1465-71
Gestational trophoblastic disease: What have we learned in the past decade? (Jones). 1990;162:1286-95
Immunocytochemical localization and messenger ribonucleic acid concentrations for human placental lactogen in amnion, chorion, decidua, and placenta (Sakbun et al). 1990;162:1310-7
Immunohistochemical localization of epidermal growth factor receptor during implantation in the rabbit (Hofmann and Anderson). 1990;162:837-41
Increasing quantity of maternal immunoglobulin G in trophoblastic tissue before the onset of normal labor (Akin et al). 1990;162:1154-7
Prediction of residual trophoblastic tissue in first-trimester abortions and low levels of human chorionic gonadotropin β-subunit (Schiff et al). 1990;162:797-801
Uterine large granular lymphocytes: A possible role in embryonic implantation? (King and Loke). 1990;162:308-10 (Clin. opinion)
Trophoblastic tumor
Diagnostic and therapeutic curettage in gestational trophoblastic disease (Schlaerth et al). 1990;162:1465-71
Tubal pregnancy; *see* Pregnancy, tubal
Tubal sterilization; *see* Sterilization, tubal
Tumor necrosis factor
Cytokine-mediated regulation of ovarian function: tumor

necrosis factor α inhibits gonadotropin-supported progesterone accumulation by differentiating and luteinized murine granulosa cells (Adashi et al). 1990;162:889-99

Twins

Antenatal origin of neurologic damage in newborn infants. II. Multiple gestations (Bejar et al). 1990;162:1230-6

Birth weight discordancy in male-first and female-first pairs of unlike-sexed twins (Blickstein and Weissman). 1990;162:661-3

Blood sampling and transfusion in utero suggested in the pumping twin (Jakobi and Zimmer) (Letter); (Stiller and Romero) (Reply). 1990;162:1632-3

Hydramnios in twin pregnancy (Machin and Still). 1990;162:1625-6 (Letter)

Intrauterine fetal growth in concordant twin gestations (Rodis et al). 1990;162:1025-9

Maternal death caused by HELLP syndrome (with hypoglycemia) complicating mild pregnancy-induced hypertension in a twin gestation (Neuman et al). 1990;162:372-3

Maternal serum α-fetoprotein in twin pregnancy (Johnson et al). 1990;162:1020-5

Prepregnancy weight status, prenatal weight gain, and the outcome of term twin gestations (Brown and Schloesser). 1990;162:182-6

Treatment of twins with hydramnios (Thorp and Chescheir) (Letter); (Lange and Harman) (Reply). 1990;162:1625-6

U

Ultrasonic diagnosis

An analysis of antenatal tests to detect infection in preterm premature rupture of the membranes (Ohlsson and Wang). 1990;162:809-18 (Curr. dev.)

Aneurysm of the vein of Galen: a new cause for Ballantyne syndrome (Ordorica et al). 1990;162:1166-7

Antepartum ultrasonic diagnosis of cord presentation (Pelosi). 1990;162:599-601 (Letter)

Are choroid plexus cysts an indication for second-trimester amniocentesis? (Benacerraf et al). 1990;162:1001-6

Assessment of fetal response to exercise in pregnancy (Rafla) (Letter); (Morrow) (Reply). 1990;162:1129-30

Benefits of placental biopsies for rapid karyotyping in the second and third trimesters (late chorionic villus sampling) in high-risk pregnancies (Holzgreve et al). 1990;162:1188-92

Biparietal diameter/femur length ratio as predictor of trisomy 21 (Kopelman and Miyazawa). 1990;162:1346 (Letter)

Cervical length may change during ultrasonographic examination (Sonek et al). 1990;162:1355-7 (Letter)

Changes in blood gas, acid-base parameters require adjustment (Soothill) (Letter); (Ferrazzi et al) (Reply). 1990;162:1350-1

Changes in uterine blood flow during human pregnancy (Thaler et al). 1990;162:121-5

A comparison between umbilical artery velocimetry and standard antepartum surveillance in hospitalized high-risk patients (Lowery et al). 1990;162:710-4

Contractions of the inner third of the myometrium (de Vries et al). 1990;162:679-82

The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: a prospective blinded study (Maulik et al). 1990;162:1518-25

Direct determination of the ovine fetal umbilical artery blood flow waveform (Irion and Clark). 1990;162:541-9

Doppler examination of the middle cerebral artery in anemic fetuses (Vyas et al). 1990;162:1066-8

Doppler measurements of fetal and uteroplacental circulations: relationship with umbilical venous blood gases measured at cordocentesis (Bilardo et al). 1990;162:115-20

Early prenatal diagnosis of gastroschisis with transvaginal ultrasonography (Guzman). 1990;162:1253-4

An evaluation of the efficacy of Doppler flow velocity waveform analysis as a screening test in pregnancy (Newnham et al). 1990;162:403-10

Evaluation of the lemon and banana signs in one hundred thirty fetuses with open spina bifida (Van den Hof et al). 1990;162:322-7

Femur length shortening in the detection of Down syndrome: Is prenatal screening feasible? (Nyberg et al). 1990;162:1247-52

Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention (Crombleholme et al). 1990;162:1239-44

Fetal weight error perpetuated (DuBose). 1990;162:876 (Letter)

First-trimester diagnosis of exencephaly (Kennedy et al). 1990;162:461-3

Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7

Flow velocity waveforms of the vascular system in the anemic fetus before and after intravascular transfusion for severe red blood cell alloimmunization (Mari et al). 1990;162:1060-4

Hydramnios in the third trimester of pregnancy: a change in the distribution of accompanying fetal anomalies as a result of early ultrasonographic prenatal diagnosis (Ben-Chitrit et al). 1990;162:1344-5 (Letter)

Incorporating endovaginal ultrasonography into the overall gynecologic examination (Goldstein). 1990;162:625-32 (Clin. opinion)

Intracranial teratoma: prolonged neonatal survival after prenatal diagnosis (Dolkart et al). 1990;162:768-9

Is office use of vaginal ultrasonography feasible? (Timor-Tritsch). 1990;162:983-5 (Clin. opinion)

Maternal indomethacin therapy in the treatment of polyhydramnios (Mamopoulos et al). 1990;162:1225-9

Mathematic form corrected (Habekovic) (Letter); (Sabbagha) (Reply). 1990;162:1351

Middle cerebral artery blood flow in normal and growth-retarded fetuses (Veille and Cohen). 1990;162:391-6

Neonatal growth assessment score: a new approach to the detection of intrauterine growth retardation in the newborn (Deter et al). 1990;162:1030-6

Prediction of fetal anemia by measurement of the mean blood velocity in the fetal aorta (Nicolaides et al). 1990;162:209-12

Prenatal diagnosis of intracerebellar hemorrhage: case report (Jennett et al). 1990;162:1472-5

Prenatal diagnosis of valvar aortic stenosis by Doppler echocardiography and magnetic resonance imaging (Hata et al). 1990;162:1068-70

Randomized prospective trial comparing ultrasonography and pelvic examination for preterm labor surveillance (Lorenz et al). 1990;162:1603-10

The relationship between the umbilical artery systolic/diastolic ratio and umbilical blood gas measurements in spec-

Ultrasonic diagnosis—cont'd
imens obtained by cordocentesis (Weiner). 1990;162:1198-202
Results of ultrasonography not in agreement (Weinraub et al). 1990;162:596-7 (Letter)
Sonographic findings in the prenatal diagnosis of bladder exstrophy (Jaffe et al). 1990;162:675-8
Ultrasonographic estimation of fetal weight in the clinically macrosomic fetus (Hirata et al). 1990;162:238-42
Ultrasonography and external cephalic version at term (Donald and Barton). 1990;162:1542-7
Ultrasonography-guided early amniocentesis in singleton pregnancies (Hanson et al). 1990;162:1376-83
Vaginal ultrasonographic assessment of cervical length changes during normal pregnancy (Kushnir et al). 1990;162:991-3
Vaginal ultrasonography in the diagnosis of ectopic pregnancy (Frishman and Luciano) (Letter); (Timor-Tritsch) (Reply). 1990;162:1640-1
The value of Doppler assessment of the uteroplacental circulation in predicting preeclampsia or intrauterine growth retardation (Jacobson et al). 1990;162:110-4

Umbilical arteries
A comparison between umbilical artery velocimetry and standard antepartum surveillance in hospitalized high-risk patients (Lowery et al). 1990;162:710-4
The diagnostic efficacy of the umbilical arterial systolic/diastolic ratio as a screening tool: a prospective blinded study (Maulik et al). 1990;162:1518-25
The effect of indomethacin on the pulsatility index of the umbilical artery in human fetuses (Moise et al). 1990;162:199-202
Fetal umbilical blood gas values as diagnostic criteria (Weiner) (Letter); (Warren et al) (Reply). 1990;162:1124-5
Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7
The relationship between the umbilical artery systolic/diastolic ratio and umbilical blood gas measurements in specimens obtained by cordocentesis (Weiner). 1990;162:1198-202

Umbilical arteries, animal
Direct determination of the ovine fetal umbilical artery blood flow waveform (Irion and Clark). 1990;162:541-9

Umbilical cord
Abruptio placentae after percutaneous umbilical cord sampling: a case report (Feinkind et al). 1990;162:1203-4
Antepartum ultrasonic diagnosis of cord presentation (Pelosi). 1990;162:599-601 (Letter)
The ferning test for detection of amniotic fluid contamination in umbilical blood samples (Chao et al). 1990;162:1207-13
The influence of drugs with β-adrenergic actions on prostacyclin production of human umbilical cord vessels (Lippert et al). 1990;162:288-90 (Letter)

Umbilical cord blood; *see* **Fetal blood**

Umbilical veins
Umbilical vein oxytocin (Goodlin) (Letter); (Carey and Reddy) (Reply). 1990;162:1125-6

Ureter
Modified cystoscopy to evaluate unilateral traumatic injury of the ureter during pelvic surgery (Lin and Iwata). 1990;162:1343-4 (Letter)

Uric acid
Significance of uric acid clearance in preeclampsia (Yoshimura et al). 1990;162:1639-40 (Letter)

Urinary incontinence
Urinary incontinence in community-dwelling women: clinical, urodynamic, and severity characteristics (Fantl et al). 1990;162:946-52

Urinary incontinence, stress
The conservative management of patients with symptoms of stress incontinence: a randomized, prospective study comparing weighted vaginal cones and interferential therapy (Oláh et al). 1990;162:87-92

Urine
Relation of rate of urine production to oxygen tension in small-for-gestational-age fetuses (Nicolaides et al). 1990;162:387-91

Urodynamics
Urinary incontinence in community-dwelling women: clinical, urodynamic, and severity characteristics (Fantl et al). 1990;162:946-52

Uterine contraction
Comparative evaluation of uterine response to exercise on five aerobic machines (Durak et al). 1990;162:754-6
Contractions of the inner third of the myometrium (de Vries et al). 1990;162:679-82
The effect of disopyramide on uterine contractions during pregnancy (Tadmor et al). 1990;162:482-6
Warning symptoms, uterine contractions, and cervical examination findings in women at risk of preterm delivery (Copper et al). 1990;162:748-54

Uterine diseases
Effect of the menstrual cycle on detection and typing of human papillomavirus in uterine cervical cells (McNicol et al). 1990;162:1037-41

Uterine inertia
Controlling refractory atonic postpartum hemorrhage with Hemabate sterile solution (Oleen and Mariano). 1990;162:205-8

Uterine neoplasms
The antiestrogenic effect of cigarette smoking in women (Baron et al). 1990;162:502-14 (Curr. dev.)
Biochemical evaluation of endometrial biopsies by magnetic resonance spectroscopy—preliminary data (Raman et al). 1990;162:1511-7
Estrogen replacement therapy and the risk of endometrial cancer: remaining controversies (Rubin et al). 1990;162:148-54
Evaluation of unfavorable histologic subtypes in endometrial adenocarcinoma (Wilson et al). 1990;162:418-26
Predictive value and prevalence (Kürzl) (Letter); (Patsner) (Reply). 1990;162:871-2
Preoperative assessment of fragment D-dimer as a predictor of postoperative venous thrombosis (Olt et al). 1990;162:772-5
Use of serum CA 125 measurement in posttreatment surveillance of early-stage endometrial carcinoma (Patsner et al). 1990;162:427-9

Uterine neoplasms, animal
Designing a schedule of progestin administration in the control of endometrial carcinoma growth in the nude mouse model (Mortel et al). 1990;162:928-36

Uterine perforation
Pregnancy hemoperitoneum and placenta percreta in a patient with previous pelvic irradiation and ovarian failure (Pridjian et al). 1990;162:1205-6

Uterine prolapse
The conservative management of patients with symptoms of stress incontinence: a randomized, prospective study comparing weighted vaginal cones and interferential therapy (Oláh et al). 1990;162:87-92
Sacrospinous ligament fixation at the time of transvaginal hysterectomy (Cruikshank and Cox). 1990;162:1611-9
Uterine rupture
Uterine rupture after treatment of Asherman's syndrome (Hulka) (Letter); (Deaton et al) (Reply). 1990;162:1352-3
Uterus, abnormalities
Evaluation of hysteroscopic management of the septate uterus (Simpson). 1990;162:598-9 (Letter)
Pneumatometra (Muram et al). 1990;162:1282-3
Uterus, analysis
Disseminated intravascular coagulopathy and adult respiratory distress syndrome: life-threatening complications of hysteroscopy (Jedeikin et al). 1990;162:44-5
Hysteroscopy and laparoscopy in women with menorrhagia (Fraser). 1990;162:1264-9
Uterus, blood supply
Changes in uterine blood flow during human pregnancy (Thaler et al). 1990;162:121-5
Flow velocity waveforms in uterine and umbilical arteries during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1990;162:1193-7
Uterus, blood supply, animal
Relationship between placental location and uterine vascular resistance (Perales) (Letter); (Kofinas) (Reply). 1990;162:1362
Uterus, drug effects, animal
Reduction of postoperative adhesions in the rat uterine horn model with poloxamer 407 (Leach and Henry). 1990;162:1317-9
Uterus, physiology
Comparative evaluation of uterine response to exercise on five aerobic machines (Durak et al). 1990;162:754-6
Uterus, physiopathology
Management of severe postpartum hemorrhage by intrauterine irrigation with prostaglandin E_2 (Peyser and Kupferminc). 1990;162:694-6
Uterus, surgery
Myomectomy as a reproductive procedure (Smith and Uhlir). 1990;162:1476-82

V

Vacuum extraction
Neonatal and maternal outcome in low-pelvic and midpelvic operative deliveries (Robertson et al). 1990;162:1436-44
Vagina
Autotransfusion during cesarean section (Zichella and Gramolini). 1990;162:295 (Letter)
Early prenatal diagnosis of gastroschisis with transvaginal ultrasonography (Guzman). 1990;162:1253-4
Is office use of vaginal ultrasonography feasible? (Timor-Tritsch). 1990;162:983-5 (Clin. opinion)
Is pH test paper as accurate as the electronic measurement of the pH of vaginal secretions? (Thomason et al). 1990;162:1213-4
Sacrospinous ligament fixation at the time of transvaginal hysterectomy (Cruikshank and Cox). 1990;162:1611-9
Vaginal ultrasonographic assessment of cervical length changes during normal pregnancy (Kushnir et al). 1990;162:991-3
Vaginal creams, foams and jellies
Maternal spermicide use and adverse reproductive outcome: a meta-analysis (Einarson et al). 1990;162:655-60
Vaginal diseases
Vaginal bleeding and diethylstilbestrol exposure during pregnancy: relationship to genital tract clear cell adenocarcinoma and vaginal adenosis in daughters (Sharp and Cole). 1990;162:994-1001
Vaginal examination; *see* **Physical examination**
Vaginal hysterectomy; *see* **Hysterectomy, vaginal**
Vaginal neoplasms
Interstitial radiotherapy for the treatment of advanced or recurrent vulvar and distal vaginal malignancy (Hoffman et al). 1990;162:1278-82
Vaginal bleeding and diethylstilbestrol exposure during pregnancy: relationship to genital tract clear cell adenocarcinoma and vaginal adenosis in daughters (Sharp and Cole). 1990;162:994-1001
Vaginitis
Statistical evaluation of diagnostic criteria for bacterial vaginosis (Thomason et al). 1990;162:155-60
Valvar aortic stenosis; *see* **Aortic valve stenosis**
Vascular endothelium; *see* **Endothelium, vascular**
Vascular resistance
The relationship between experimentally determined litter size and maternal blood pressure in spontaneously hypertensive rats (Ahokas and Sibai). 1990;162:841-7
Vascular resistance, animal
Relationship between placental location and uterine vascular resistance (Perales) (Letter); (Kofinas) (Reply). 1990;162:1362
Vasoconstriction
Endothelin increases cytoplasmic calcium and myosin phosphorylation in human myometrium (Word et al). 1990;162:1103-8
Vasopressin

THERAPEUTIC HYSTEROSCOPY: Indications and Techniques

Edited by **Alvin M. Siegler**, M.D.; **Rafael F. Valle**, M.D.; **Hans J. Lindemann**, M.D.; and **Luca Mencaglia**, M.D.

This new title gives you the precise "how-to" information you need to master accepted therapeutic applications of the hysteroscope.

- *extensive illustrations (many in full color) demonstrate the hysteroscopic appearance of a problem as well as step-by-step techniques for diagnosis and treatment*
- *reviews instrumentation, accessories, and distending media as well as maintenance of hysteroscopes*
- *covers abnormal uterine bleeding, infertility, sterilization, and other conditions*

March, 1990. Approx. 224 pages, 360 illustrations. (Book Code: **05504**) About **$89.00** (U.S.); $115.75 (Can.)

New 2nd Edition!

ZUSPAN AND QUILLIGAN'S MANUAL OF OBSTETRICS AND GYNECOLOGY

Edited by **Jay D. Iams**, M.D.; **Frederick P. Zuspan**, M.D.; and **Edward J. Quilligan**, M.D.; with 27 contributors.

Completely updated and revised, with a new outline format for easier access to information.

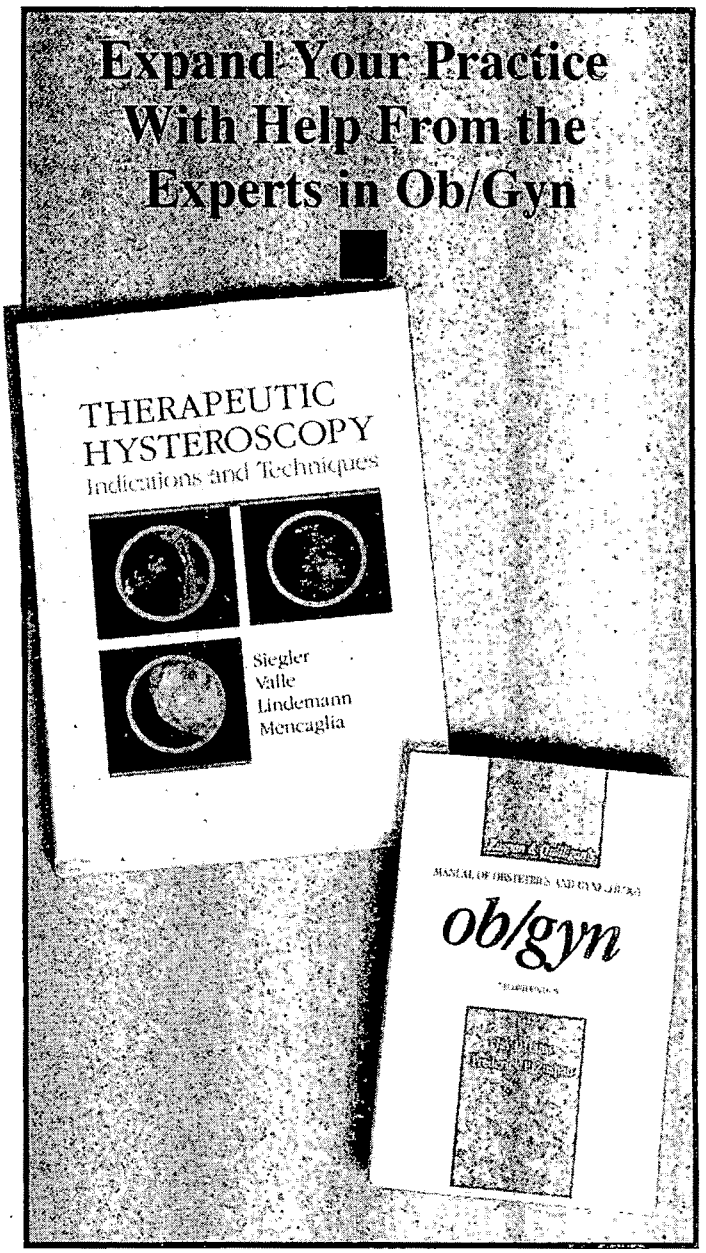
- *more specific pharmacologic information*
- *new review questions and answers following each chapter to reinforce key points and assist in Board-exam preparation*
- *expanded coverage of breast feeding and contraception*

January, 1990. Approx. 400 pages, 105 illustrations. (Book Code: **05476**) About **$24.95** (U.S.); $32.50 (Can.)

New!

CLINICAL ATLAS OF GYNECOLOGY

By **J.L.H. Evers** and **M.J. Heineman**



Gain a sound, basic knowledge of the practice of gynecology with this full-color line art atlas.

- *short descriptions of clinical situations are accompanied by ample illustrations and a clinical comment*
- *case histories are adapted from real-life situations, and include rarities as well as everyday clinical problems*
- *includes photomicrographs, MRI, CT, and ultrasound images*

February, 1990. Approx. 192 pages, extensively illustrated. (Book Code: **05852**). A Bunge publication. About **$35.00** (U.S.); $45.50 (Can.)

Your comprehensive reference guide to a decade of valuable clinical information . . .

Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

Now you have easy access to 10 years of clinical information, indexed in one convenient source — the Ten-Year Cumulative Index to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY.

This hard-cover index is a comprehensive guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the Journal from 1978 through 1987 (volumes 130 to 157). These influential, peer-reviewed papers are indexed both by subject and by author in this 800-page volume.

The Cumulative Index features:

- 4,331 subject headings, containing 24,126 references. Each subject entry lists the complete article title, author(s), volume, page, and year of publication.
- 22,456 author entries, listing contributor, respective article title, author-to-author referral, volume, page, and publication date.

The Cumulative Index is a great time-saver for locating information on clinical topics of immediate or historical significance in obstetrics and gynecology. There's no need to search for index issues from each year.

Order this important reference guide for your personal library!

CHAIRPERSON–
OBSTETRICS/GYNECOLOGY

Temple University School of Medicine is seeking a Chairperson for its Department of Obstetrics and Gynecology. The Department, located in the new Temple University Hospital and its affiliates, is in a rapid growth phase. Opportunity for faculty and program development exists. The applicant should have demonstrated leadership capabilities, proficiency in administration, teaching and research as well as serving as a role model for clinical training. Temple University is an equal opportunity, affirmative action employer. Further information can be obtained from and applications sent to:

Christer Carlsson, MD, Ph.D
Chairman, Search Committee
Department of Anesthesiology
Temple University School of Medicine
3401 N. Broad Street
Philadelphia, PA 19140.

Chairman
Department of Obstetrics and Gynecology
St. Paul's Hospital
Vancouver, B.C.

St. Paul's Hospital is presently seeking a Chairman for the Department of Obstetrics and Gynecology. This is a geographic full time appointment which requires a candidate with a background in teaching, administration, clinical care and research. An appointment will be made at the appropriate University level.

St. Paul's Hospital is a 575 bed, acute care, University of British Columbia affiliated hospital, located in downtown Vancouver. The Department of Obstetrics and Gynecology supports active inpatient programs including an obstetrical service of 2,500 deliveries per year, an infertility clinic, as well as inpatient and outpatient gynecology programs which support a large internship and residency program.

Inquiries and applications should be accompanied by a Curriculum Vitae. Preference will be given to Canadian citizens and permanent residents.

Applications should be sent to:

Dr. Thomas F. Ward
Vice President Medicine & Program Coordination
Room 333, Comox Building
St. Paul's Hospital
1081 Burrard Street
Vancouver, B.C.
V6Z 1Y6.

OB-GYN

BC/BE OB-GYN sought for full service, 260-bed community hospital in San Francisco's dynamic South of Market area.

- Excellent opportunity to join busy, growing practice.
- Competitive salary and benefits package.

ST. LUKE'S HOSPITAL

Send C.V. to:

Walter Kopp
St. Luke's Hospital
3555 Army Street
San Francisco, CA 94110
(415) 641-6543

FACULTY POSITION
MATERNAL-FETAL MEDICINE
St. Louis, Missouri

St. John's Mercy Medical Center seeks a fourth perinatologist for its fully accredited residency program and one of the midwest's largest obstetrical services. There are over 6000 deliveries per year at St. John's and our 35 bed NICU has over 800 admissions annually.

This 859 bed community, not-for-profit, teaching hospital offers an outstanding professional environment with excellent compensation and benefits. Emphasis will be on resident education and expansion of the maternal transport service. Contact Phil Gilbert, Administration. St. John's Mercy Medical Center, 615 South New Ballas Road, St. Louis, MO 63141. 314-569-6116

KAISER PERMANENTE

OBSTETRICIAN-GYNECOLOGIST

The Permanente Medical Group, Inc., of San Jose, California is looking for BC/BE physicians for immediate openings in the OB/GYN Department. Positions available either at the main facility in San Jose, or at satellite medical offices in Gilroy. The young, dynamic, department is still growing and currently has seventeen physicians and two nurse practitioners. Our outstanding benefits package includes full coverage malpractice insurance. San Jose and Gilroy share excellent access to Bay Area cultural and recreational activities.

Recent salary advances allow extremely competitive compensation starting with the first year of employment.

For more information, please contact:

Jerome L. Nehemiah, M.D.
Chief, Department of Ob/Gyn
The Permanente Medical Group, Inc.
260 International Circle
San Jose, CA 95119
or telephone: 408-972-6180 (collect)

PERINATOLOGIST

Denver, Colorado

Rose Medical Center, Denver, Colorado is seeking a second BE/BC perinatologist to work full-time in a 400-bed private community hospital adjacent to the University of Colorado Health Sciences Center. With 3,600 deliveries per year, and 27 University Residents rotating through the department annually, Rose is the major private teaching affiliate of the University.

Responsibilities include, primary patient care, private consultation, physician, resident, and nursing education, clinical research, and a limited private practice in perinatology. This individual can expect frequent interaction with the Maternal/Fetal Division at the University of Colorado, and will be eligible for an appropriate clinical appointment at the University. All clinical responsibilities will be shared with the current full-time perinatologist at Rose. Additional call coverage is provided by other perinatologists in the Denver metro area.

A competitive salary guarantee is being offered, with excellent fringe benefits including malpractice insurance.

Qualified applicants, individuals completing fellowship in June, 1991, should forward CV's to:

Robert E. Wall, M.D., Chairman
Department of Obstetrics & Gynecology
Rose Medical Center
4567 East Ninth Avenue
Denver, Colorado 80220
Telephone: (303) 320-2077

SPECIAL DELIVERIES. SPECIAL CHALLENGES.

The Southern California Permanente Medical Group invites you to join a unique prepaid health care program. Our multispecialty group practice is a partnership composed of and managed by SCPMG physicians.

Board eligible/certified **PERINATOLOGISTS** are needed for our high-volume obstetric services which handles 3,000-6,000 deliveries per year. Opportunities exist both to join and create high risk services.

There are positions available to practice Perinatology exclusively. Perinatologists who are interested in performing other aspects of obstetrics and gynecology may do so. We also have positions available for Endocrinologists and General Obstetrician-Gynecologists. University affiliation and clinical research are encouraged.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (800) 328-5278. If calling from outside of California, please (800) 541-7946 or send curriculum vitae to: Irwin P. Goldstein, M.D., Associate Medical Director, SCPMG, Dept. 006, Walnut Center, Pasadena, CA 91188-8013. Equal Opportunity Employer M/F/H
